Drugs have their limitations. They can never be all there is to the treatment of the schizophrenic person. They may be helpful in promoting restitution but they sometimes have toxic effects. Moreover, they do not enlighten the patient about his problems, inform him how to adapt, or help him to take advantage of opportunities or to accept his limitations. They do not repair self-esteem, nor do they repair the damage that the patient may have done to his friends and family. They cannot get him a job, they cannot make mothers or mothers-in-law change their minds, they don't handle traffic violations, and they cannot teach him to do something he couldn't do before. Obviously, therefore, treatment must include someone who has a relationship with the schizophrenic person and who tries to help him with the practical affairs of everyday living.

Limitations of Nondrug Therapies

It may be taken as an axiom that any form of treatment may have toxic effects if used at the wrong time, for the wrong person, or in the wrong amounts. For example, milieu therapy can have toxic, antitherapeutic effects, particularly when techniques and methods developed for neuroses and character disorders are indiscriminately applied to psychotic patients.

For patients who have defects in perception, attention, and information processing or who are disorganized and hyperaroused, the typical milieu ward, with its high stimulus input, lively group meetings, role diffusion, searches for hidden meanings, loud music, and inability to distinguish staff from patients by dress may constitute a toxic dose of environmental stimulation (17).

Delayed toxic effects may also occur. Patients tend to conform to an institutional culture, whatever it may be. What happens when patients adjust to a hospital society that is radically different from the outside world?

Psychotherapy can make some patients worse, especially when there is a negative transference or a serious countertransference. Destructive acting out may occur when inhibitions are lifted. Therapist hostility to families and significant others can have serious toxic effects and make a bad situation worse, provoke a divorce, or drive the patient into an untenable position. Some patients may protract therapy indefinitely to cling to transference gratifications or may even become sexually involved with the therapist.

CONCLUSIONS

There is as yet no universally effective and lasting cure for schizophrenia. Many patients can be helped to regain their premorbid level of functioning, but reordering a pathological personality style is a task of a different order, one that is difficult, if not impossible, to achieve by the methods currently available. Hence a major point of strategy is defining goals for each patient. It is important to distinguish between trying to achieve or maintain restitution and trying to remake the patient. It is also important to remember that what is good for one patient may not be good for another; that what helps in the early stages of treatment may not help at all later on; that measures aimed, for example, at getting the patient a job may have no effect on his temper tantrums. It is therefore essential to define clearly what the goals are and to plan specific interventions accordingly—and to make appropriate adjustments as treatment progresses.

The days when a practitioner would prescribe one therapy (e.g., drug therapy, psychotherapy, recreational therapy, milieu therapy, or a therapeutic community)—or a mélange of all therapies—for all patients should be gone forever. There should be thoughtful adjustment of goals to meet the needs of the various parties involved and the situation of the moment. For each patient there are several parties and many moments.

The Isaac Ray Award

The American Psychiatric Association invites nominations for the Isaac Ray Award for 1977. This award, in memory of Margaret Sutermeister, is presented to a person (psychiatrist, attorney, or someone from a discipline related to human behavior) who has made outstanding contributions to forensic psychiatry or to the psychiatric aspects of jurisprudence. The purpose of this award is to promote better understanding between the law and psychiatry. The award, which will be presented at the Convocation of Fellows at the Annual Meeting of the American Psychiatric Association in Toronto, Canada, in May of 1977, includes an honorarium of $2,000. The recipient agrees to present his or her work at an institution of higher learning (or other suitable location) and to present the manuscript for publication. The presentation will be located and timed to give maximum exposure to students and practitioners of law and medicine and to other professionals.

Nominations are requested by the deadline of October 1, 1976, from any interested professional, and may be submitted to: Naomi Goldstein, M.D., Chairperson, Isaac Ray Award Board, 15 West 81st St., New York, N.Y. 10024.

The Identification and Treatment of Adult Brain Dysfunction

BY HENRY B. MANN, M.D., AND STANLEY I. GREENSPAN, M.D.

The authors hypothesize that adults who have had minimal brain dysfunction as children constitute a distinct diagnostic entity, adult brain dysfunction (ABD), which may exist alone or with a variety of other psychiatric syndromes. Patients with ABD share a basic impairment in ability to focus attention effectively; they may have different personality structures, symptom complexes, and behavioral patterns. However, with medication that corrects this impairment, remarkable improvement in the presenting symptoms and in the ability to work in therapy may occur, leading to changes in personality structure and behavior.

THE SYNDROME OF minimal brain dysfunction (MBD) in children has been well described by a number of authors (1–3). In children, MBD is defined behaviorally by the presence of short attention span, distractibility, anhedonia, and occasional poor impulse control, hyperactivity, and lack of response to reward and punishment. Investigators differ as to whether the primary deficit is lack of response to reward and punishment (1) or attentional difficulties (2, 3). Our experiences support an attentional difficulty as the primary deficit; however, we also recognize that a difficulty in the capacity to focus attention effectively would compromise the capacity to respond to social cues and expectable social reward and punishment consequences.

Initially, the syndrome was thought to represent a developmental lag. Investigators have proposed many causes of MBD, including perinatal trauma, head injury, encephalitis, poisoning, and hereditary tendencies (1–3). More recent biochemical approaches have attempted to define the syndrome as resulting from a defect in amine metabolism (1), and this shift of opinion has led to an increased focus in the past few years on what happens to these children when they become adults. Recent reports in the literature suggest that adults who had characteristics of the MBD syndrome while they were children may show a variety of neurotic and characterologic symptoms (4–7).

Morrison and Stewart (7) studied the families of 50 hyperactive children and found that 14 parents had been hyperactive as children. Of the 14, 6 were alcoholic, 1 was a sociopath, 3 had severe depression, 1 was a psychotic epileptic, 2 were heavy drinkers, and 1 was symptom free.

Cantwell (4) reported that 10% of the parents of 50 hyperactive children had been hyperactive as children. These 10% had prominent symptoms of either alcoholism, sociopathy, or hysteria.

Clinicians have also been paying increasing attention to the question of what happens to the MBD children in adolescence and adulthood (8–14). Menkes and associates (10) reported on 14 follow-up patients who had been seen as children in the Johns Hopkins Child Psychiatry Outpatient Clinic and retrospectively diagnosed as having MBD on the basis of their clinical records. The average age at time first seen was 7.5 years and at time of follow-up was 32.5 years. When these patients were reexamined, 4 were institutionalized with a psychotic diagnosis, and 2 were retarded and dependent on their families. Of the remaining 8, all of whom were self-supporting, 2 had spent time in an institution for delinquent boys, 1 in a hospital for the retarded, and 1 in jail. Eleven patients in this group were examined neurologically—8 had "definite evidence of neurologic dysfunction," usually consisting of terminal intention tremor and minimal uncoordination. None had received medication as part of his treatment. Unfortunately, the use of a retrospective diagnosis weakens the conclusions of the Menkes and associates study.

Mendelsohn and associates (11) studied 83 teenagers who had been diagnosed as hyperactive 2–5 years earlier. At follow-up over 50% of the teenagers were described as hyperactive, impulsive, rebellious, destructive, having low self-confidence, having temper tantrums, having failed one or more grades, or being involved in lying, fighting, and stealing. Of these, 18% had appeared at least once in juvenile court. Most of the children in their study had received medication and therapy for at least a brief time, but unfortunately the authors did not describe the relationship between symptomatic response to treatment and presence or absence of severe characterologic problems at follow-up.

There are several brief reports on the use of medication as part of the treatment of adults who are suspected of having minimal brain dysfunction (13–15). Gross and Wilson (13) reported the case of a 38-year-old mother of 3 hyperactive children. This woman had difficulty in organizing her thoughts and her life: "She talked in short, disconnected phrases, frequently flit-

Dr. Mann is Director of Adolescent Inpatient Psychiatry, Elmcrest Psychiatric Institute, Portland, Conn.; he is also in private practice. Dr. Greenspan is Chief, Mental Health Study Center, National Institute of Mental Health, Adelphi, Md. Address reprint requests to Dr. Mann, 54 Liberty St., Madison, Conn. 06443.

ting from one thought to another with no connecting bridge. She gave the appearance of being scatterbrained because of staccato, disorganized speech, yet it was clear she was an intelligent, thoughtful woman" (pp. 60–61). This patient was placed on 50 mg of imipramine twice a day, which led to "considerable improvement in the disorganization, both verbally, which could be detected by outsiders, and in terms of feeling better put together" (p. 61).

Arnold and associates (14) report the use of *d*-amphetamine in the treatment of a 22-year-old college student who reported being restless and having difficulty concentrating. His symptoms responded well to the medication. There are, however, no reports in the literature that systematically consider the issues of diagnosis and treatment of adults who may be manifesting a wide variety of symptoms and who may have had a version of MBD as children.

Although it has been hypothesized that MBD children have a wide variety of psychiatric disorders in adulthood, we would like to propose here a different hypothesis: people who have had MBD as children constitute a distinct diagnostic entity as adults, which we call adult brain dysfunction (ABD) and which may exist alone or with a wide variety of other psychiatric syndromes.

We further propose that ABD may at times be difficult to diagnose because 1) the predisposing dysfunction in childhood may be so mild as to be undetected or 2) it may be compensated for by characterologic strengths. We suspect, therefore, that many children with either mild or moderate to severe attention difficulties coupled with an unusual degree of creativity, intelligence, and capacity for interpersonal relationships (based on optimal early relationship patterns with parents who were sensitive to their needs) do not experience manifest psychiatric difficulty until they encounter the stresses of adult life.

Defining a new diagnostic entity helps us in finding a specific treatment for it. We believe it is important to learn how to identify this entity because, as we shall illustrate, there is a distinct medical treatment that, when used in conjunction with psychotherapy, leads to vastly improved prognoses for otherwise very difficult cases. In the following two brief case reports, we will present only the details that highlight the issues we wish to stress.

CASE REPORTS

Case 1. A 29-year-old single woman who owned a dress shop presented to one of us (H.B.M.) after 1 year of treatment in individual and group therapy. She originally entered therapy because she felt depressed (low self-esteem, feelings of inadequacy, loss of feelings of pleasure, early morning wakening, intermittent tearfulness, and a general sense of despair). She also had symptoms of severe social anxiety. When there was essentially no improvement after 1 year of therapy, the group therapist, a social worker, referred the patient for psychiatric consultation in connection with using medication for her depression.

Further history taken at the time of referral for consideration of medication treatment revealed that she had felt depressed and "stupid" all her life. She had done poorly in school, having to repeat the first, third, and fourth grades, and she recalled having had a short attention span and difficulty concentrating in the past as well as in the present. She recalled that she was easily distractible as a child and felt this description still applied. She said, "I can't organize and make plans, I can't think in large blocks, I can't hold onto my ideas." She also recalled being very active as a child but did not describe herself as a "wall climber."

In addition, she described anxiety reactions that were like panic attacks—they could occur as often as 1–4 times a day in any situation where she had to approach new tasks or confront people on issues that had any emotional meaning to her. With her panic attacks she described palpitations, dizziness, stomach churning, difficult breathing, muscle tension in the back and neck, and momentary feelings of confusion regarding who she was and where she was. She particularly emphasized her lifelong feeling of stupidity.

Communication with the patient's mother confirmed that as a child the patient had had a very short attention span and was very distractible. There were none of the other clinical signs of MBD, such as hyperactivity, poor impulse control, or labile mood. There was no family history of learning disability, depression, alcoholism, sociopathy, or hysteria. Interestingly, during the patient's childhood and adolescence neither the patient nor her family had ever considered the possibility of an emotional or learning difficulty. They viewed her characteristics, as most families would, as individual differences and "nothing that caused us that much trouble." As an adult she was also able to do quite well superficially (e.g., run a successful business, lead an active social life).

During the early interviews the patient always appeared to be well-groomed and attractive—even rather dramatic. She was mildly depressed and anxious, and she had difficulty completing her thoughts. Otherwise, her presentation was unremarkable.

Because of her history of early learning disorders and her present difficulty with concentration and depression, the patient was given a provisional diagnosis of ABD and placed on a trial of 10 mg of imipramine in the morning, which was increased over a 3-day period to 25 mg each morning. The patient began responding to treatment almost immediately and after the third day expressed the view that she was dramatically improved. She said, "I always felt things were out there; now things are inside my head and nothing distracts me. I can begin organizing things." Her panic attacks and social anxieties disappeared, and in her psychotherapy she was able to explore her feelings and relationships more effectively. Follow-up over a 1½-year period showed continued marked improvement.

Case 2. The patient, a "mild alcoholic," was a 28-year-old man who worked as a janitor in a local department store. He complained of anxiety attacks during which he felt panicky and fearful of dying, his heart pounded, and he had cold sweats; he also had occasional diarrhea that had been diagnosed as functional colitis. The anxiety attacks and multiple phobic elaborations that he developed were most intense whenever he had to speak up within a group of people.

The patient appeared to be a neatly dressed, extremely fidgety (constantly moving his hands and feet), and markedly anxious young man. He jumped quickly from one subject to

another and seemed to be quite disorganized in his thinking. He could stay on one thought for only a few minutes and then moved on to something else. His speech was rapid and had a pressured quality. However, his associations were not loose or tangential. His affect was appropriate but tense.

Family history revealed that a younger sister had been hospitalized with psychotic depression, an older brother had recurrent depressions, and his father had had chronic alcoholism.

The patient's history revealed that he "couldn't sit still in class—the teacher called me hyper." The patient had repeated the fifth and ninth grades. He was unable to retain what he read or heard. His report cards showed problems from first grade on with learning skills, attention span, and disruptive behavior. In adolescence the patient began to avoid most family and social gatherings and began drinking "to calm down."

Because of the patient's history of difficulty with learning and concentrating and his style of relating during the initial interviews, he was provisionally diagnosed as having adult brain dysfunction. The patient was started on 50 mg of imipramine each morning and was seen once a week in supportive psychotherapy. After one week he appeared much less fidgety and more coherent in his thinking (e.g., he was able to finish thoughts, he did not shift subjects as quickly, and there was a marked reduction in the pressure of his speech). He reported feeling better, having no further panic attacks, feeling less subjectively depressed, and cutting back his drinking to two cans of beer a day. He began working on the phobic difficulties and some marital problems and made a marked improvement in his capacities to deal with his marriage and job. Remission of the initial symptoms has now continued for over 1 year; the patient is still on his medication. With the approval of his therapist, he terminated psychotherapy 4 months ago. At the time of the last interview the patient was much improved and had been able to run for office in a local volunteer organization and win by a two-thirds majority.

These cases illustrate several characteristics that the patients have in common: 1) a history of early learning disorder with short attention span; 2) diffuse severe symptoms in adulthood, with elements of anxiety and depression or their equivalents prominent; 3) a rather remarkable, dramatic alteration in the symptom picture with imipramine; and 4) a mental status exam characterized by rapid flow of speech and many shifts of subject but without overt indicators of psychotic thinking (e.g., circumstantiality, ideas of reference, etc.).

One of the authors (H.B.M.) and several colleagues, in a general adult and child psychiatric practice in a middle- to upper-middle-class suburban community, have seen over 20 cases in the last 2 years that are similar to these 2 cases. Individuals who had the characteristics listed above presented with different ego structures and symptoms and would ordinarily have fit into different diagnostic categories—the neuroses, character disorders, or borderline psychotic states.

An important point to note is that the medication led to more organized, focused attention without feelings of euphoria or increased excitement. If these feelings occur, the possibility of a misdiagnosis should be considered. Medicated patients may, however, experience more feelings of depression due to better concentration.

These cases show that medication produced a quick change in capacity for focused attention and concentration (e.g., "I can sit and read," "I remember more," "I can think more clearly," "I can experience more feelings inside me"). This increased capacity to focus and concentrate led to symptomatic relief and, more importantly, helped these patients use psychotherapy to begin altering characterologic and neurotic problems. Patients with borderline features were also able to develop a capacity to use therapy to deal more effectively with their feeling states and interpersonal relationships. We postulate that this occurs because the basic impairment in ability to focus attention effectively manifests itself in a difficulty in focusing attention not only on the external world (e.g., reading, learning, perceiving, and understanding other people) but also on the "internal world" of feelings and thoughts (e.g., experiencing subtle emotional states, solving problems, and integrating such polarities as love and hate and good and bad).

Although the research on minimal brain dysfunction in children indicates that brain dysfunction in an adult may have a partially biological etiology, the primary dysfunction influences the development of the total personality structure and must therefore also be considered from a psychodynamic perspective. While psychodynamic issues will not be considered in any detail at this time, issues related to feelings of inadequacy, low self-esteem, counterphobic defenses, and any other consequence of an inability to focus attention, control impulses, and maintain sensitive, empathetic relationships with others should be considered in cases with a primary diagnosis of ABD.

However, psychodynamic considerations raise an important question: why is the adult version of this disorder different from the childhood version? As indicated, the adult manifests this disorder with diffuse symptoms related to depression and anxiety, often without impulsiveness and hyperactivity. We hypothesize that the adult has gained sufficient ego maturation, particularly for internalized control, to regulate some of the secondary symptoms such as hyperactivity and impulsiveness. Because the adult also has new demands (e.g., separation from parents, sexual intimacy, responsibility), his basic impairment still makes him vulnerable to the development of symptoms. The greater capacity for internalized control and self-perception may partially account for the prominence of depressive symptoms in adults with ABD.

In bright or talented children or in children who have had a very supportive and understanding environment, minimal brain dysfunction may never become manifested in a clinically pathological state until adulthood, with its attendant demands and stresses (as in case 1). It is also important to note that many children with short attention spans, distractibility, and learning deficits grow up to live reasonably happy and produc-

tive adult lives without evidence of serious psychopathology, but at present we have not distinguished the factors that lead to this outcome.

DIAGNOSIS OF ABD

It is difficult to diagnose adult brain dysfunction because many of its accompanying symptoms readily fit into other diagnostic categories, e.g., alcoholism, hysteria, depressive illness, borderline states, impulsive personality, sociopathic personality, and explosive personality. The key clinical issue is to help the patient elucidate the distinguishing factors that characterize this disorder.

Indications of any symptoms commonly associated with MBD in childhood should lead to further careful history taking. The first author found it helpful to go back and interview the parents of even a middle-age adult because the patient did not remember enough about his capacity for concentrating, learning, and controlling his impulses. Where possible report cards and school records were studied. The behavior questionnaire reported by Eisenberg (15) is quite useful in helping the patient and his family to assess his present and past functioning. A history of delayed developmental milestones, hints of even minimal brain trauma either during the birth process or early in life, and, more generally, any indications of impaired functioning in neurophysiological regulation and focusing are clues that should cause the interviewer to raise additional questions.

The response to a trial of one of three medications that appear to increase functional norepinephrine levels is very important. In these two cases, imipramine was used. *d*-Amphetamine and methylphenidate have also been used successfully. A full response to medication includes relief of the presenting symptoms and an increased ability to focus attention. Paradoxically, in some patients there actually may be increased depression as they look at themselves more clearly and become more aware of their feelings and their life situation.

Also important in making this diagnosis is a family history of learning disorders (i.e., short attention span and distractibility), poor impulse control, alcoholism, and periodic endogenous depression. It has been our experience, confirmed by other researchers (4, 7), that these symptom clusters seem to be common in the families of those children and adults who have this syndrome.

A history of chronically poor attention span or inability to focus concentration, which may be the most important diagnostic clue, will often be denied and/or rationalized by the patient. The patient will talk about everything else—his depression, anxiety, fears, nightmares, inability to sleep—but will not explain that when he reads a book he cannot focus for more than five minutes at a time and often has difficulty retaining what he does read. A positive interviewer-interviewee alliance with specific empathetic questioning about this area of the patient's life is necessary. This information is not easily volunteered, and as a result the diagnosis of ABD is infrequently considered. The clinician must also determine whether the difficulty in focusing attention is chronic (and probably secondary to MBD) or situational (and probably secondary to depression or anxiety). The possibility of a history of poor attention span may also be indicated by the patient's mental status exam. Patients with ABD, during the initial interview, may evidence restlessness and anxiety along with a marked difficulty in staying on one subject and developing a train of thought.

TREATMENT

The medical and psychotherapeutic treatment of ABD involves the use of either antidepressants or stimulants and psychotherapy. However, the medication dosages and responses and the relationship between the management of the medication and the psychotherapeutic process are sufficiently complex to warrant separate presentation in the literature.

The importance of employing caution in making the diagnosis of ABD and avoiding overzealous use of medication should be stressed. Many children have attentional and learning difficulties and even the associated symptoms of hyperactivity and poor impulse control as a result of developmental lags, anxiety states, neurotic patterns, character problems, and borderline to psychotic ego structures on predominantly functional grounds rather than as a result of MBD.

Their subsequent psychiatric difficulties as adults may represent a continuation of these primarily functional disorders of childhood or represent strictly functional disorders of adulthood. For many patients, long-term psychotherapy without medication or with drugs other than those we have mentioned is indicated. Misdiagnosing a strictly functional disorder requiring long-term psychotherapy as ABD will invariably support the patient's defensive rationalizations against self-inquiry and further convince him of the reality of his often unconscious negative self-image. Caution, care, and flexibility regarding diagnostic impressions are crucial.

CONCLUSIONS

The prevalence figures for minimal brain dysfunction or the symptoms associated with it in children run as high as 5% in some studies (1), and it is possible that the adult variety of MBD may also have a high prevalence in our population. It is our hope that clinicians will begin looking for ABD not only to further clarify its nature and elaborate on it but also because it is our impression that there is a specific treatment which is helpful and often a necessary antecedent to successful psychotherapy.

Reversal of Tricyclic-Overdosage-Induced Central Anticholinergic Syndrome by Physostigmine

BY PAUL C. HOLINGER, M.D., AND HAROLD L. KLAWANS, M.D.

Although there is evidence that the delirium, stupor, coma, and seizure-like activity seen in overdosage with tricyclic antidepressants and antiparkinson drugs are due to the central anticholinergic activity of these agents, patients with overdosage of these drugs are still frequently misdiagnosed. The authors present a case of reversal of anticholinergic-drug-induced prolonged coma, myoclonus, and choreoathetosis by physostigmine. This report supports the anticholinergic basis of the clinical manifestations of such overdosages, provides information on the role of acetylcholine and dopamine in psychiatric and movement disorders, and illustrates dramatically the need for accurate diagnosis and treatment.

IT IS NOTABLE that until recently, tricyclic antidepressant poisoning has received relatively little attention. This is somewhat puzzling because one would expect a substantial incidence of overdosing by depressed patients, and their tricyclic antidepressant medication is a natural vehicle. We would also expect the phenothiazines and antiparkinson medications to be involved in poisonings because both groups of drugs are often self-administered by severely disturbed psychiatric patients. In addition, antiparkinson drugs are often self-administered by parkinsonian patients, a high percentage of whom have been shown to be demented later in the disease (1).

The purpose of this report is to draw further attention by psychiatrists and internists to the syndrome resulting from overdosage with these medications; cases are still frequently misdiagnosed and poorly treated, a situation particularly tragic because medical treatment is readily available and early treatment may be lifesaving.

It is well known that anticholinergic drugs such as atropine and scopolamine, as well as over-the-counter medications containing these drugs, can cause a toxic confusional state (central anticholinergic syndrome) characterized by agitation, disorientation, visual and auditory hallucinations, anxiety, purposeless movements, delirium, stupor, and coma (2–13). Accompanying this toxic confusional state is peripheral anticholinergic activity manifested by flushing, dry mouth, constipation, mydriasis, temperature elevation, motor incoordination, and tachycardia. The peripheral manifestations as well as the confusional state are dose related.

Several reports have noted that psychotropic drugs such as tricyclic antidepressants, phenothiazines, and anticholinergic antiparkinson agents can produce a toxic confusional state manifested by delirium, stupor, and coma (14–20) and shown to be due to central anticholinergic effects (10, 21–26). There is much information in the recent psychiatric literature about the delirium manifestations of the syndrome, but little is mentioned about the coma and its lifesaving treatment.

The physiological basis of the central anticholinergic syndrome is the competitive inhibition of the neurotransmitter acetylcholine at central cholinergic receptor sites (7, 8). Physostigmine salicylate is an anticholinesterase that crosses the blood-brain barrier. By competitively inhibiting the acetylcholine-destroying enzyme acetylcholinesterase, physostigmine causes acetylcholine to accumulate at cholinergic sites and is therefore capable of producing effects equivalent to continuous stimulation of cholinergic fibers throughout the central and peripheral nervous systems (7, 8).

Physostigmine has been shown to reverse the central anticholinergic syndrome and peripheral anticholinergic effects of atropine, scopolamine, and anticholinergic antiparkinson drugs (4–6, 10, 22, 26–28). Recently, many reports have also indicated that physostigmine reverses the delirium, stupor, and coma characterizing the central anticholinergic syndrome of the tricyclic antidepressants, phenothiazines, anticholinergic antiparkinson drugs, and combinations of these drugs (21–25, 29–33); in addition, physostigmine reverses the peripheral anticholinergic effects of these medications. Cardiac complications are a particularly hazardous possibility in tricyclic antidepressant use (16, 34–41); however, the mechanism of action by which the tricyclic antidepressants produce cardiac complications and the therapeutic role of physostigmine are unclear.

Dr. Holinger is with the Institute for Psychosomatic and Psychiatric Research and Training, and Dr. Klawans is Director, Division of Neurology, Michael Reese Hospital and Medical Center, Chicago, Ill. This work was supported in part by the Michael Reese Medical Research Institute Council, Chicago, Ill.

The EEGs for this study were performed at the Samuel E. Hokin EEG Laboratory, Michael Reese Medical Center.

In addition to delirium, stupor, and coma characterizing the central anticholinergic syndrome of the psychotropic drugs mentioned above, seizure-like activity has often been reported. Such movements have more accurately been identified as myoclonic jerks and choreoathetosis and are reversible with physostigmine (23).

The purpose of the present paper is threefold. In addition to drawing attention to a potentially life-threatening situation, we also wish to report on a specific case of prolonged coma due to tricyclic antidepressant overdosage that was reversible with physostigmine. The patient manifested the longest duration of coma before reversal by physostigmine that we are aware of in the literature. The case demonstrates the necessity of accurate diagnosis of the central anticholinergic syndrome and the lifesaving treatment physostigmine provides in even terminal stages. Finally, the reversal of the myoclonic jerks and choreoathetosis by physostigmine in this patient confirms the reports of other investigators and provides additional information on the role of acetylcholine and dopamine in movement disorders.

CASE REPORT

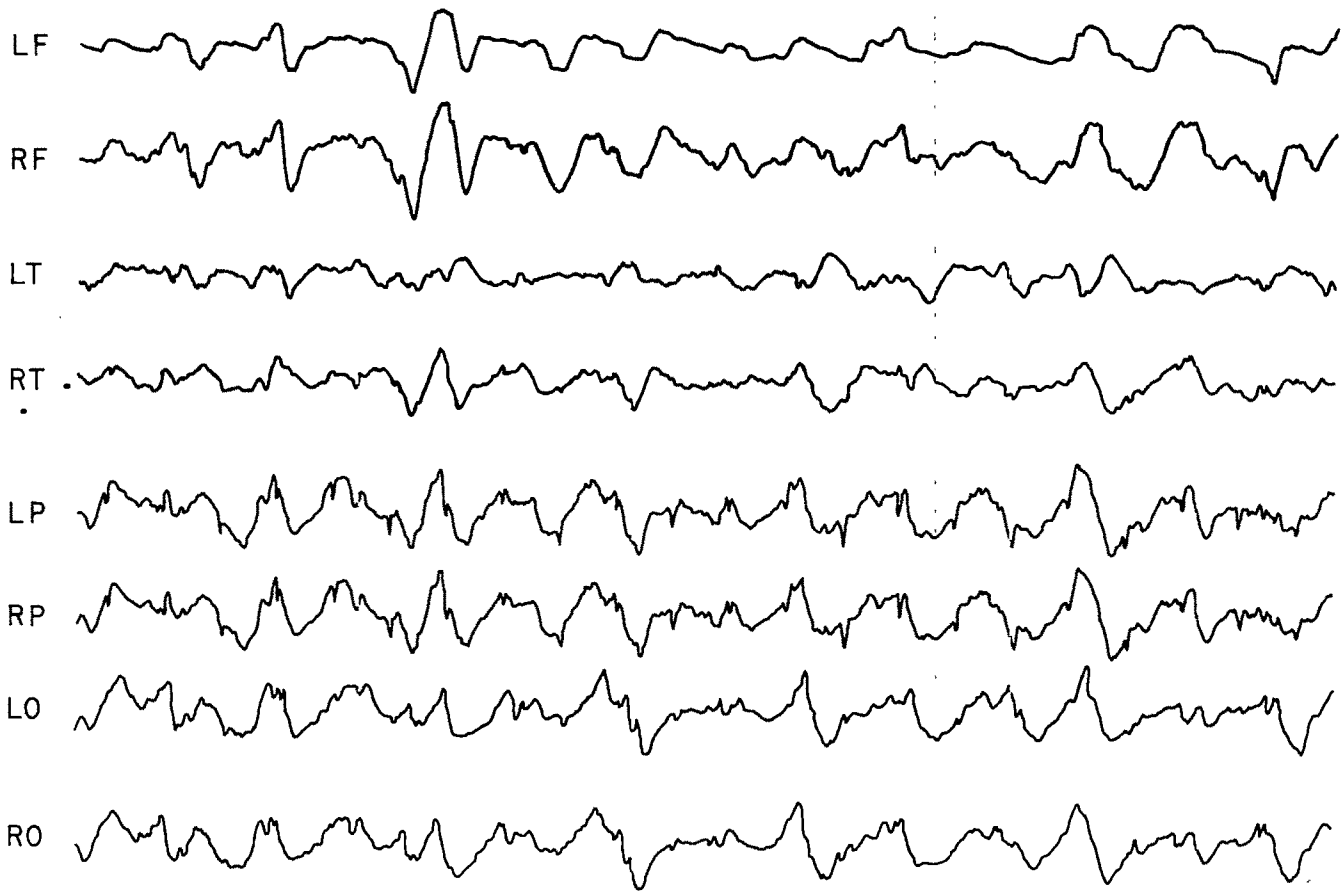
Case 1. The patient, a 55-year-old woman with many previous psychiatric hospitalizations for depression, was discharged from a psychiatric hospital 4 days before being brought to the emergency room of Michael Reese Hospital following an overdose of an unknown but large amount of amitriptyline. There was also evidence of ingestion of unknown but small amounts of chlorpromazine and benztropine. In the emergency room (ER) she was found to be in a coma and responsive only to deep pain. After lavage and the extraction of many pills she was transferred to the intensive care unit (ICU) 4 hours after being seen initially in the ER.

On admission to the ICU her vital signs were as follows: blood pressure, 150/110; pulse, 86 and regular; respirations, 20 (spontaneous); temperature, 96°F (rectal). The patient was well hydrated, and physical findings were unremarkable with the exception of her neurological examination. She was responsive only to deep pain, which was manifested by grimacing of her face. Her pupils reacted equally to light and were conjugate and midline. The tone of her muscles was flaccid and lacked spontaneous movement. Her deep tendon reflexes were 1+ and symmetrical. The Babinski sign was absent bilaterally, and oculocephalic and oculovestibular reflexes were present. Laboratory data indicated normal electrolytes and complete blood count (CBC); blood gases were as follows: pH, 7.30; pCO_2, 59.9; CO_2, 30; and HCO_3, 28.9. EKG was normal.

During the patient's first 24 hours in the ICU she was noted to have myoclonic jerks and choreoathetoid movements of all extremities, greater in the arms than in the legs. These occurred intermittently and were mistakenly reported as seizures by several observers. The patient was given 100 mg of phenobarbital intramuscularly, followed by 60 mg every 4 hours. The movements diminished somewhat but continued irregularly. Sometime later during the patient's first 24 hours in the ICU she was intubated due to worsening hypoventilation. She was noted to be fighting the respirator but usually triggered it by her own spontaneous breathing.

During hours 24–48 in the ICU the patient's coma continued, with intermittent myoclonic jerks and the appearance of occasional dysconjugate gaze. Her temperature rose to 102–103°F (rectal), and antibiotics were administered. Her blood pressure increased to 200/120. Phenobarbital during the second day in the ICU was decreased to 30 mg four times a day.

Hours 48–60 in the ICU were marked by continued temperature elevation of 101–103°F (rectal), with one recording of 104°F. Basilar crepitations were heard bilaterally, and the following day the chest X ray, which until then had been normal, showed bilateral infiltrates.



It was the 60th hour in the ICU and about the 64th hour of known coma that an accurate diagnosis was made and appropriate treatment with physostigmine was begun. The patient was initially given 1 mg of physostigmine intravenously. Within 3 minutes of physostigmine administration she opened her eyes, and a few minutes later she was able to spontaneously move her arms. During the next several minutes she gradually lapsed back into her previous state of responsiveness only to deep pain. One mg of physostigmine was administered subcutaneously every hour during the next 24 hours, increased to 4 mg every hour intravenously for 24 hours, then changed to 4 mg every 2 hours for the next 36 hours before discontinuing. One mg of methylscopolamine was administered every 4 hours intravenously for the 3½ days of physostigmine administration to counteract peripheral effects of physostigmine. Phenobarbital was discontinued.

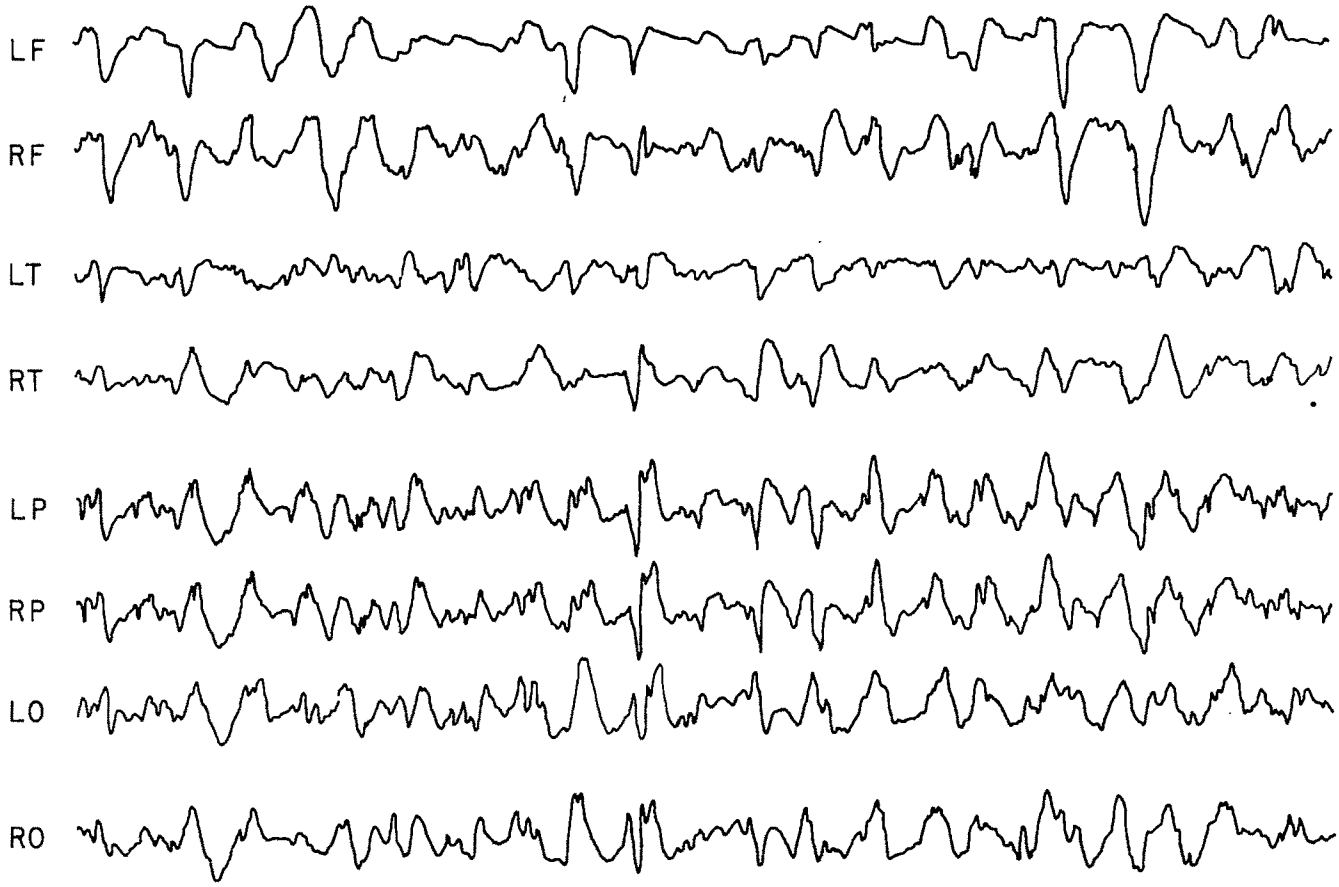
During the first day of physostigmine use the patient's EEG showed generalized irregular ½–2-second activity that was most marked in the right frontal area, with faster frequencies following physostigmine injection (see figures 1 and 2). The myoclonic jerks and choreoathetoid movements ceased after physostigmine administration with only occasional diminished recurrence between injections; these stopped a day after the initial injection. During the 5 days following initial use of physostigmine the patient's state of consciousness varied between periods of alertness and response to verbal commands to periods of responsiveness only to deep pain. She gradually improved, however, and 8 days after physostigmine administration she was extubated; extubation before this had not been possible due to the continued inability of the patient to maintain spontaneous respirations because her respiratory efforts were often marked by apneic periods. Her temperature decreased, her lungs gradually cleared, and she was transferred to a psychiatric hospital 12 days after her admission to the ICU.

DISCUSSION

Although this case demonstrates several typical and atypical features of the central anticholinergic syndrome, two aspects in particular deserve discussion. First is the issue of the prolonged length of the coma and its rapid reversal with physostigmine. Coma has been noted in the central anticholinergic syndrome (4, 5, 14–16, 19, 23–30, 34, 37, 38, 42, 43) and shown to be reversible with physostigmine (4, 5, 23–30). Nobel and Matthew (15) reported coma in 51 of the 100 patients they studied. The longest period of coma was 18 hours; only 6 other patients were in coma for more than 8 hours, with a mean of 6.4 hours. Their

FIGURE 1
Patient's EEG Before Administration of Physostigmine*

*This figure shows spontaneous monopolar EEG activity dominated by 1–2-cycles-per-second activity. L=left; R=right; F=frontal; T=temporal; P=parietal; and O=occipital.



treatment was based on general supportive care.

Stark and Bethune (42) presented a case of combined amitriptyline and amylobarbitone poisoning in which the patient was unconscious for more than 4 days and recovered with treatment consisting of forced diuresis and supportive measures. Rasmussen (14), in discussing his series of 67 cases of tricyclic antidepressant poisoning and successful treatment of 1 case with pyridostigmine, noted the ineffectiveness of blood-clearing methods in such cases and suggested that the forced diuresis of Stark and Bethune was effective as treatment of the poisoning caused by amylobarbitone only. These case reports (15, 42) reflect the wide range of duration of coma due to central anticholinergic syndrome seen throughout the literature; as is often seen, Stark and Bethune's case does not represent a pure central anticholinergic syndrome because the clinical picture was complicated by ingestion of other drugs, in this situation a barbiturate.

The clinical picture of recovery from coma with physostigmine also varies from immediate reversal of peripheral and central anticholinergic effects to reversal of such effects over days with varying levels of consciousness. The variation in recovery is often dependent on the amount of physostigmine administered and when it is administered.

The present case illustrates prolonged coma of more than 64 hours secondary to ingestion of tricyclic antidepressants, phenothiazines, and antiparkinson drugs, complicated by iatrogenic use of phenobarbital to control seizure-like activity. Within minutes after physostigmine administration the patient regained consciousness after this prolonged coma, with subsequent varying levels of consciousness until complete recovery about 8 days later. The unique nature of this case, i.e., immediate but brief return to consciousness following a prolonged period of coma with eventual complete recovery, dramatically illustrates the need for accurate diagnosis and treatment of the central anticholinergic syndrome and the capacity of physostigmine to be lifesaving even after prolonged coma. Phenobarbital may have contributed to the depressing of this patient's consciousness and respiration, although to what extent is unclear, as is the role of this patient's treatment in alleviating the possible toxic effects of phenobarbital.

FIGURE 2
Patient's EEG After Administration of Physostigmine*

*This figure shows a marked increase in faster EEG activities 15 minutes after 1 mg of physostigmine was administered intravenously. L=left; R=right; F=frontal; T=temporal; P=parietal; and O=occipital.

The second issue to be discussed involves the myoclonus and choreoathetosis seen in this patient and the cessation of such movements following physostigmine treatment. Many reports have noted seizure-like activity, including myoclonus and choreoathetosis, in the central anticholinergic syndrome (14–17, 19, 23, 24, 38, 43, 44). Nobel and Matthew (15) found that 43 of 100 patients with acute poisoning by tricyclic antidepressants manifested "twitching and/or jerky movements," most frequently seen in comatose patients and least common in those fully conscious; 4 patients were noted to have convulsions. Recently, increasing attention has been focused on seizures occurring in patients receiving therapeutic doses of tricyclic antidepressants (45, 46). Burks and associates (23) suggested that the movement disorders associated with the central anticholinergic syndrome may often be inaccurately classified as seizures, resulting in treatment with barbiturates or diazepam, which may further depress respiration and level of consciousness. These authors reported 2 cases of coma from tricyclic antidepressant poisoning in which myoclonus and choreoathetoid movements were documented and reversed by physostigmine. The present report documents a case of central anticholinergic syndrome manifesting prolonged coma and myoclonus and choreoathetoid movements that were initially mistaken for seizures and treated with phenobarbital; these signs were reversed by physostigmine.

Our case report also supports Burks and associates in providing evidence for the hypothesis of a decrease in acetylcholine relative to dopamine in the basal ganglia in choreiform states, as suggested by Klawans and Rubovits (47). Studies of patients with Huntington's chorea have demonstrated a relationship between chorea and an anticholinergic state. It has been found (47–49) that physostigmine reduced chorea in Huntington's chorea but that benztropine, a centrally active anticholinergic agent, increased chorea. Levodopa, a dopamine precursor, has been reported to increase chorea in some patients with Huntington's chorea (50, 51). Thus the hypothesis developed that chorea may result from an imbalance of acetylcholine and dopamine with a resulting decrease in acetylcholine relative to dopamine in the basal ganglia. By decreasing acetylcholine and increasing amines, including dopamine, the tricyclic antidepressants affect both sides of this balance, with chorea as a predictable

clinical manifestation. Physostigmine may reverse tricyclic antidepressant-induced chorea, as seen in this and other case reports, by increasing acetylcholine through anticholinesterase activity.

Myoclonus was seen in this case and is often reported in cases of tricyclic antidepressant poisoning. Klawans and associates (52) showed that large doses of 5-hydroxytryptophan increased brain serotonin levels and produced myoclonic movements. Methysergide, a serotonin antagonist, abolished the movements. The myoclonus seen in our patient and others may be the result of the decreased serotonin uptake into serotonin neurons and subsequent increase in serotonin at the synapse caused by tricyclic antidepressants.

Hofheimer Research Prize

The American Psychiatric Association invites applications for its annual Hofheimer Prize for outstanding research in psychiatry and mental hygiene. The award is given for a book, monograph, or series of related papers reporting the findings of major studies or research programs that have been published or accepted for publication. The award carries with it an honorarium of $750 and will be presented at the Convocation of Fellows at the Association's 1977 Annual Meeting.

Applicants must be U.S. or Canadian citizens not older than age 50. If a group of co-workers is involved, their median age must be less than 50, and the majority of them must be U.S. or Canadian citizens. Any professional person who has done creative work in this area is eligible. However, the work must have been completed or published within the last three years (on or after July 1, 1973).

To apply, submit six copies of the book, monograph, or series of related papers (or reprints) to: Joel J. Elkes, M.D., Chairman, Hofheimer Prize Board, American Psychiatric Association, 1700 Eighteenth Street, N.W., Washington, D.C. 20009. Entries will be acknowledged, but will not be returned. The deadline for submission is December 31, 1976, and any entry to be considered must be in Washington, D.C. by that date.

Tracking Difficulties and Paranoid Ideation During Hashish and Alcohol Intoxication

BY FREDERICK TOWNE MELGES, M.D.

In a double-blind study using each subject as his own control, 6 normal subjects smoked 20 mg of THC within 10- and 45-minute periods ("fast" and "slow" conditions, respectively). Each subject also received placebo and doses of alcohol calculated to be as intoxicating as the THC doses. In fast conditions, THC induced greater difficulties with tracking information over time, greater disruptions of self-other interpersonal perceptions, and more persecutory ideation than did alcohol or placebo. Similar but less marked differences were found in the slow conditions. As hypothesized, changes in tracking difficulties, self-other metaperspectives, and persecutory ideation were substantially and significantly correlated.

O wad some Power the giftie gie us
To see oursels as others see us!

—ROBERT BURNS
Ode to a Louse

DISTORTED PERSPECTIVES of others' views of the self are common in paranoid reactions (1, 2). Could such distorted views arise from difficulties with tracking information over time? That is the central question of this paper.

Previous research (3) has shown a substantial and significant relationship between temporal disorganization and incipient delusional ideation (feelings of influence, grandiosity, and persecution) when normal subjects were given high doses of THC under controlled conditions to induce temporal disorganization. The specific focus of the present paper is on possible relationships between difficulties with tracking information over time, disjunctive self-other metaperspectives, and persecutory ideation during THC and alcohol intoxication.

DEFINITIONS, RATIONALE, AND HYPOTHESIS

"Difficulties with tracking information over time" refers to problems with immediate memory and maintaining attention over time. Examples include loss of one's train of thought, inability to remember what was just said, and blocking. Such lapses of immediate or "working" memory have been found to be prominent during marijuana intoxication (4) and also have been emphasized as a central cognitive deficit in schizophrenia (5–7).

The self's view of the other's view of the self is defined as a metaperspective by Laing and associates (8). The term "disjunctive self-other metaperspectives" means that a person has difficulty comparing his own view of himself (i.e., his perspective on himself) with how he thinks others are viewing him (i.e., his metaperspective of others' view of himself).

"Persecutory ideation" refers to unwarranted suspicions about being controlled or manipulated by others (1, 2). In this paper, the terms "persecutory" and "paranoid" will be used synonymously. As has been previously proposed (1), persecutory ideation often emerges when a threat of loss of self-control interacts with predictions of control from others. The result of such an interaction is heightened self-consciousness about what others are thinking or doing in relation to the self.

The basic idea of the present research was that persecutory ideation is likely to occur when difficulties with tracking information over time disrupt ongoing self-other metaperspectives. That is, a person is likely to become paranoid when he is concerned about how others are viewing him and is having difficulty keeping track of such information. Thus, the specific hypothesis was that difficulties with tracking information over time are associated with disjunctive self-other metaperspectives, which in turn are related to the emergence of persecutory ideation.

This hypothesis is a corollary of a previously proposed general postulate that temporal disorganization

Revised version of a paper presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

Dr. Melges is Chairman and Chief of Psychiatry, Santa Clara Valley Medical Center, San Jose, Calif. Address reprint requests to the author at the Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, Calif. 94305.

This work was supported in part by Alcohol, Drug Abuse, and Mental Health Administration grants MH-19918 from the National Institute of Mental Health and AA-0498 from the National Institute on Alcohol Abuse and Alcoholism.

The author wishes to note that this study was conducted in collaboration with J.R. Tinklenberg, M.D., C.M. Deardorff, Ph.D., N.H. Davies, Ph.D., R.E. Anderson, M.D., and C.A. Owen, all of the Stanford University School of Medicine.

is associated with the emergence of delusionlike ideation (3). The present research, although conducted during the course of testing the above postulate, is focused on the more specific relationships between tracking difficulties and disjunctive interpersonal perceptions that are possibly related to persecutory ideation. In order to test the hypothesis, high doses of THC were used to induce tracking difficulties in normal subjects, and comparably intoxicating doses of alcohol were employed as controls.

PILOT STUDIES AND EXPERIMENTAL APPROACH

Pilot studies indicated that a cigarette containing 20 mg of THC smoked within 10 minutes produces marked tracking difficulties. (This dosage approximates the amount of THC in hashish.) This condition was labeled "fast hashish" and was the primary experimental manipulation. In order to study lesser degrees of tracking difficulties, a cigarette containing the same amount of THC was smoked over a 45-minute period ("slow hashish" condition). In effect, this was a lower dose because it was distributed over time. Neither of these THC conditions produced delirium, i.e., subjects were oriented to calendar time, place, and person and could read and comprehend inventory statements.

It should be emphasized that the fast conditions for both THC and alcohol represent unusual circumstances that are not relevant to the customary use of cannabis or alcohol in social settings. Fast conditions were compared with slow conditions in order to differentiate marked alterations in consciousness from lesser degrees of alterations induced by these drugs.

In order to control for a general intoxicating factor that might disrupt self-other metaperspectives independently of tracking difficulties, we did pilot work to find doses of alcohol, administered in both fast and slow conditions, that were comparably intoxicating to the THC conditions. Doses of 120 ml of 95% alcohol were found to be suitable and were not associated with marked tracking difficulties in the pilot studies. These alcohol doses, along with a placebo condition, also served to control for experimental set and setting, which might influence self-other metaperspectives.

METHOD

Subjects

Considerable care was taken in the selection of our 6 subjects. They were all men in their twenties who were experienced but not excessive users of cannabis and alcohol, had no psychiatric history, were not in a stressful period of their lives, were actively employed or going to school, were judged by their peers to have good interpersonal relations and psychological health, and showed no detectable predisposition to delusory ideation on a battery of tests. Informed consent was obtained before proceeding.

Experimental Design

Since the details of the experimental design and procedures have been published previously (3), they will be only briefly outlined here. The 6 subjects were given placebo and comparable doses of THC and alcohol under fast and slow conditions. The THC cigarettes, supplied by the National Institute of Mental Health, contained 20 mg of (−)-Δ-tetrahydrocannabinol. The comparable dose of alcohol was computed to be 120 ml of 95% alcohol (1.75 ml/kg of body weight). Double-blind procedures were used; each subject was his own control for the following randomly presented dose conditions (separated by one week to avoid carryover effects): fast hashish, fast alcohol, slow hashish, slow alcohol, and placebo.

Subjects were tested at baseline (predrug), peak (maximum intoxication, i.e., 30 minutes after smoking hashish and 50 minutes after drinking alcohol), and "coming down" (3 to 3½ hours after drug consumption). On each experimental day, the subject drank a cocktail of aromatic lemon-flavored carbonated beverage (with or without alcohol) and smoked a cigarette (with or without active THC). Because ingested alcohol is absorbed more slowly than THC, drinking took place earlier than smoking to ensure that peak testing would be at the maximum level of intoxication for each drug. Placebo was randomly presented as "fast" or "slow."

Only 1 subject was tested on each experimental day. Testing was done by an experienced psychologist in the presence of a medical assistant and took place in a comfortable living room atmosphere. Between test sessions, the subject was free to listen to music, read, or interact socially with the tester and medical assistant, both of whom remained supportive but noncommittal and open-ended. The subject, the tester, and the medical assistant knew whether fast or slow conditions were to take place, but they did not know whether the drug was THC, alcohol, or placebo.

Testing

This report will focus primarily on three inventories: tracking difficulties, self-other metaperspectives, and persecutory ideation. Subjects responded to each of the inventory statements in terms of their reactions for "the last few minutes" on a seven-spaced semantic differential-type scale ranging from "not at all" to "extremely" or "not at all" to "frequently," depending on the nature of the inventory. In order to avoid response sets, some items were phrased in the direction of normality (indicated by asterisks in the lists that follow) rather than toward alterations in consciousness or psychopathology.

The 12 statements in the tracking difficulties inventory have been published previously (3); examples are as follows:

1. I tend to lose my train of thought.
2. I forget what I have just said or what I intend to say.

3. My mind is racing and I cannot sort out the thoughts that I want.
4. My mind goes blank at times, as if my memory is blocked.
5. Thoughts slip away before I can quite grasp them.

The statements on the self-other metaperspectives inventory were largely derived from the work of Laing and associates (8) and, like the other inventories, were refined during the pilot studies. The statements are as follows:

1. I am having difficulties comparing my own view of myself with how I think others are viewing me.
2. There seem to be gaps in my awareness of what other people around me are doing.
3. I am unsure of what to expect from other people.
4. I'm only getting glimpses of other people around me so that I don't know quite what they're up to.
5. I care what others think of me.*
6. It's difficult for me to figure out what other people expect of me.
7. I feel that other people around me understand my inner experiences.*
8. When I interact with others, I feel confident and on top of things.*
9. I am having difficulties in getting my ideas and feelings across to other people.
10. I feel one-down or somewhat inferior to others.
11. When I am conversing with another person, what I say and what he says appears out of step.
12. Other people must be feeling the same way I am feeling.

The persecutory ideation inventory consisted of the following statements:

1. I have the feeling that I might be being tricked or manipulated.
2. I am suspicious that other people have motives that are unclear to me.
3. Something strange is going on in the world around me.
4. I feel that it is safe to trust other people right now.*

These statements are a subcomponent of a previously published inventory of delusionlike ideation (3). Such ideation was termed "delusionlike" because it was not necessarily fixed and impervious to contradiction (3).

Along with a number of other inventories, subjects also responded to a semantic differential test of emotional reactions, which was scored for negative emotions (3). In addition, they rated their peak phase of intoxication on each experimental day in terms of degrees of "highness" on a scale of 0 to 100 (0 = completely normal and 100 = completely high). Similarly, they rated their peak phase in terms of overall "pleasantness" (0 = totally unpleasant and 100 = totally pleasant).

RESULTS

The pertinent comparisons are between fast hashish and fast alcohol and between slow hashish and slow alcohol (see table 1). For these corresponding fast and slow conditions, comparable degrees of intoxication (highness), pleasantness, and negative emotions were found, indicating that neither the degree of intoxication nor emotional factors relating to experimental set or setting accounted for the differences obtained with the other inventories.

Fast hashish induced significantly greater tracking difficulties, disjunctive self-other metaperspectives, and persecutory ideation than fast alcohol, as tested by two-way analysis of variance of baseline-to-peak changes (table 1) as well as by independent Student's t tests. Slow hashish compared with slow alcohol in-

TABLE 1
Mean Baseline-to-Peak Changes for Different Dose Conditions (N=6)*

Test	Condition					F (df=4, 20)	Significance
	Fast Hashish	Fast Alcohol	Slow Hashish	Slow Alcohol	Placebo		
Tracking difficulties	25.2	8.0**	24.5	6.8**	−0.2	13.5	p<.001
Self-other metaperspectives	14.8	2.5**	6.7	−0.8	−4.2	5.5	p<.01
Persecutory ideation	5.8	1.3*	1.8	0.3	−0.2	3.6	p<.02

Aggregate Intraindividual Change Correlations Across Dose Conditions*

	Self-Other Metaperspectives	Persecutory Ideation
Tracking difficulties	.61	.57
Self-other metaperspectives	—	.88

*Average Pearson product-moment correlation coefficients, computed from intraindividual concomitant changes during each of the five experimental conditions. All coefficients are statistically significant ($p<.001$).

duced similar but less marked differences; the only significant difference was greater tracking difficulties during slow hashish (table 1). As expected, since the THC dosage in the slow hashish condition was the same as that in the fast condition but was distributed over time and was therefore essentially a lower dose, slow hashish produced fewer distortions of consciousness than fast hashish (3).

For all dose conditions, within-subject changes in the three variables (tracking difficulties, disjunctive self-other metaperspectives, and persecutory ideation) were computed. Intraindividual correlations between concomitant changes in the variables were then computed. Then, using Fisher's z transformation and the T transformation (3, 9), aggregate change correlations for all subjects were computed. These aggregate change correlations were substantial and highly significant (see table 2).

DISCUSSION

The substantial change correlations indicate that tracking difficulties, disjunctive self-other metaperspectives, and persecutory ideation are mutually interacting processes. The hypothesis was thus confirmed. The interaction of these variables can be understood by noting the items that showed the most marked baseline-to-peak increase during fast hashish compared with fast alcohol: "I tend to lose my train of thought"; "I am having difficulties comparing my own view of myself with how I think others are viewing me"; and I feel "that it is [un]safe to trust other people right now."

Hashish conditions induced greater degrees of tracking difficulties, disjunctive self-other metaperspectives, and persecutory ideation than similarly intoxicating alcohol conditions. This was particularly evident when hashish was smoked rapidly (within a 10-minute period). "Paranoid" reactions were clinically evident only in fast hashish conditions, during which 4 of the 6 subjects described themselves as "paranoid." The term "paranoid" is used advisedly, since the persecutory ideation was not necessarily fixed or systematized, but the subjects' reactions did resemble the acute unsystematized state of early delusion formation seen in psychiatric patients (1, 2).

The role of tracking difficulties in disrupting self-other metaperspectives and prompting suspiciousness is exemplified by 1 subject's report of his "paranoid" reaction in the fast hashish condition. He reported that he was only getting "chunks" of what other people around him were doing and that when he tried to "fill in the gaps" and "piece together the chunks," he came up with a host of suspicions about the missing information. He was further dismayed when he could not keep track of his suspicions in order to test them out. This rather paradoxical cognitive disorganization, characterized by a high rate of associations coupled with an inability to keep track of such associations, was present in the other paranoid reactors. We have also found it to be a common feature in retrospective accounts of so-called bad trips precipitated by cannabis in social settings (10), and it was first systematically clinically investigated and reported by Ames (10).

Tracking difficulties during THC intoxication were usually intermittent, and clinical interviews with subjects indicated that they were beyond volitional control for the most part. This intermittent loss of information about others' supposed view of the self is similar to that experienced by persons who are partially deaf, who may also have persecutory ideation (3). The intermittent loss of information may be more likely to precipitate persecutory ideation than a sustained or constant loss of information about the environment, since the person perceives fragments of how he thinks others are reacting to him and is able to pursue, at least intermittently, the implications and connections of such fragments. Acute schizophrenics who have only intermittent tracking difficulties are more likely to be paranoid than those who have a sustained inability to maintain attention over time (2, 6). That is, with sustained tracking difficulties and related problems with immediate memory, associations may become so loose that the person's thoughts wander in many different directions and a persecutory premonition therefore cannot be pursued (1, 4).

Although tracking difficulties may play an important role in contributing to the persecutory ideation during hashish intoxication and perhaps other paranoid syndromes, they are not the whole story. The attribution of a global conspiracy directed toward the self seems to be related to the telescoping of past, present, and future so that many events ordinarily separated by real time seem to be interconnected in psychological time (3). Also, as detailed elsewhere (1), the threat of loss of self-control may be the general initiating event for incipient persecutory ideation. Difficulties with tracking information over time may pose such a threat, since the person has intermittently lost volitional control over his thinking. This threat of loss of self-control may prompt the person to feel vulnerable to control from others and to attempt to predict others' plans in order to prevent their gaining control (1). Tracking dif-

ficulties may further aggravate this threat-prediction interaction, since the person who has difficulty keeping track of ongoing self-other perspectives may misconstrue the motives of other people in relation to himself. In this way, the inferences that comprise what Robert Burns called attempts "to see oursels as others see us" may go awry.

Marijuana and Hostility in a Small-Group Setting

BY CARL SALZMAN, M.D., BESSEL A. VAN DER KOLK, M.D., AND RICHARD I. SHADER, M.D.

The authors used several indices to assess the relationship between marijuana and hostility as both inner affect and verbal behavior in a small-group setting. Marijuana subjects reported a small but statistically significant decrease in hostile feelings after the introduction of a frustration stimulus. They also showed significantly less verbal hostility than placebo subjects both before and after introduction of a frustration stimulus. The authors note that research findings on marijuana and hostility are not consistent and suggest a multidetermined relationship based on dose, environment, nature of the frustration stimulus, and intraindividual factors.

THE POSSIBLE ASSOCIATION between marijuana and hostile human behavior has recently been reexamined. Originally, primarily on the basis of anecdotal evidence from law enforcement agencies, marijuana use was considered to be associated with aggressive and assaultive crimes (1–3). Early medical reports (4, 5, pp. 269–274 and 313–335) tended to dispute this correlation, as have recent reviews (6, 7). A study of ganja use in Jamaica (8) noted that, although police and popular belief associate the drug with violent crimes, most regular users are "known to be peaceful law abiding citizens."

Research focusing on marijuana and aggression has appeared only recently. Summaries of the effect of marijuana in animals have noted the variable effect of the drug in producing or quieting aggressive behavior (2, pp. 48–50; 9, 10). Increases in aggressive behavior have been reported in dogs (11) and rats (12, 13) given cannabis preparations. Decreases in aggressiveness or taming effects have been observed in mice (14) and in rhesus monkeys (15). The variable association between the active ingredients of marijuana and aggression has been attributed to a biphasic (stimulant-depressant) activity (16), a species-specific response, the dose level and frequency of administration (17), the type of active ingredient (18), and the development of tolerance with repeated doses (19).

Studies in man have been less equivocal. For example, Hollister and associates (20) noted that individuals' scores on the aggressive factor of the Clyde Mood Scale decreased after they ingested THC, the active ingredient in marijuana. Bloom (21) reported a statistically nonsignificant decrease in overall aggression, defined operationally as the amount of dummy electric shocks marijuana-intoxicated subjects administered to another subject. Tinklenberg (22) recently reviewed field and laboratory studies of marijuana and aggression and concluded that "there is no convincing evidence that the pharmacological properties of marijuana incite or enhance human aggression."

Current psychopharmacology research suggests that drugs which alter subjective mood or experience may produce different effects when taken in a social group setting than when taken individually. Marijuana is traditionally consumed in a group setting. Becker (23) detailed the process of becoming a marijuana user and stressed the interpersonal aspect of this learning process. Starting with the LaGuardia report (5, p. 247), almost all other writings about nonresearch marijuana use have reported on the social setting in which marijuana consumption often occurs (24–26). Based on research observations, Jones (27) noted that subjects behave differently when they receive marijuana when alone than they do during marijuana use in a group setting. When tested alone, subjects were quiet, relaxed, and slightly drowsy; in the group setting they evinced elation, euphoria, laughter, and a lack of sedation. Galanter and associates (28) observed in groups of intoxicated research subjects a decreased tendency to express anger, along with a decreased participation in group process. Babor and associates (29) noted that the effects of marijuana may suppress social interaction in a task-oriented research group setting; Mendelson and associates (30) studied the same subjects and found them less hostile and anxious and more friendly and carefree. In a previous pilot study, Salzman and associates (31) had observed the Mendelson and associates research groups for verbal hostile behavior. Self-ratings of hostility decreased, and sub-

Revised version of a paper presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

jects rated each other as more friendly, cooperative, and understanding. Ratings of taped verbal interaction revealed that overall hostile communications shifted from overt criticism to sarcasm as the most frequently used indirect expression of hostility. The present study was designed as a controlled follow-up of these preliminary observations.

METHOD

The subjects were 60 physically and emotionally healthy male volunteers between the ages of 21 and 30. Fifty of the subjects had some college education. All had prior experience with marijuana; more than half of the subjects smoked marijuana at least once a week and considered themselves social marijuana users. Half of the subjects experimented with hallucinogens, amphetamines, and barbiturates, but none of the subjects reported narcotic use. The mean Taylor Manifest Anxiety (32) score was 7.02, and the mean Langer Social Adjustment (33) score was 1.3. These figures suggest that these subjects were less symptomatic than previous subjects in our laboratory (34) or tended as a group to deny psychological impairment.

The overall design of the study has been described in detail elsewhere (35, 36); we will present only a summary here. The subjects, who did not know each other, were assigned to 3-person groups, each of which was randomly designated as active marijuana or placebo according to a double-blind schedule. Each 3 person group completed the study independently. Each group met for a 10-minute discussion that focused on the development of a consensus story for a neutral Thematic Apperception Test (TAT) picture (card 2). This and subsequent group discussions were videotaped with the knowledge of the subjects and were used for group process scoring. Each subject smoked completely one cigarette that contained either 2.2% THC or placebo (both provided by the National Institute of Mental Health); all subjects in each 3-person group smoked the same substance. A second group discussion was then held; the focus was on arriving at a consensus story for TAT card 10. Subjects were then told that the consensus story they had just developed was "inadequate" and they would have to arrive at a new one. This was conceived of as an experimental frustration stimulus within an interpersonal group setting. Each group then met for a third discussion.

Individual hostility levels were assessed before and after each group discussion on the Buss-Durkee Hostility Inventory (BDHI) (37) and the Symptom Checklist (SCL-90). Interpersonal behavioral (verbal) hostility during each group discussion was assessed via the hostile interpersonal rating scale (HIRS) devised in our laboratory and by Bales' Interaction Process Analysis (IPA). Ratings of group cohesion, task performance, and affects other than hostility will be presented in a separate communication.

RESULTS

The effect of marijuana on hostility as an inner affective or motivational state is summarized in table 1. Change scores on the BDHI and SCL-90 anger-hostility scale reflecting drug effect were similar for marijuana and placebo recipients. However, following the frustration stimulus, small but statistically significant decreases in hostile affect were reported by the marijuana recipients; placebo subjects' scores increased slightly.

The effect of marijuana on verbal behavioral hostility is summarized in table 2. Marijuana produced a small but statistically significant increase in sarcastic communications, as rated on the HIRS. There was a statistically significant increase in total negative verbal

TABLE 1
Hostility as an Inner Affect: Mean Change Scores for Subjects Given Marijuana (N=30) or Placebo (N=30)

Item	Scores

*** Prefrustration minus postfrustration.

behavior (measured by combined IPA scales 10, 11, and 12) following marijuana ingestion. After the frustration stimulus, both total negative verbal and sarcastic behaviors significantly decreased for marijuana subjects but increased for the placebo subjects.

In order to examine the relationship between the two methods of determining manifest verbal behavioral hostility, a correlation was computed between HIRS sarcasm change scores and the IPA raw scores for the marijuana subjects.[1] The correlations were .66 ($p<.01$) and .59 ($p<.01$) for postdrug minus predrug scores and postfrustration minus prefrustration scores, respectively. These are strong correlations for two independently derived and rated measures of behavior.

DISCUSSION

In the laboratory setting of a small-group interaction, marijuana-intoxicated subjects reported a small but statistically significant decrement in hostile feelings after frustration compared with placebo subjects, who experienced a slight increase. The present study also demonstrates a slight increase in sarcasm on the part of the marijuana-intoxicated subjects, a replication of previous findings from our laboratory. The increase in sarcastic communication correlated with, and is probably reflected by, the IPA-rated increase in negative verbal communications and was included within the overall ratings. The decreased inner affective hostility in conjunction with increased negative verbal behavior suggests that this dose of marijuana, taken in the group context, may have had a mild disinhibitory effect on the subjects, enabling them to feel less internally angry and less externally constricted in their interpersonal communications. Pepitone and Reichling (38) have noted that under such circumstances hostility is often visible.

In previous studies in our laboratory (35, 36), the frustration stimulus produced increases in hostile affect and verbal behavior in all subjects. It was not surprising, therefore, that placebo subjects demonstrated increased hostility as both affect and as verbal behavior after the frustration stimulus. Among marijuana smokers, however, hostility as an inner affective state decreased slightly, albeit significantly, as did verbal negative behavior, including sarcasm, after the frustration stimulus.

We may infer that marijuana used in laboratory group settings with a mild frustration stimulus may lead to a diminution in negative verbal interpersonal behavior and affective hostility. It has been suggested elsewhere that marijuana generally serves to inhibit the expression of violent or aggressive behavior: "Marijuana-induced relaxation of inhibitions is not ordinarily accompanied by an exaggeration of aggressive tendencies" (39). In this laboratory experiment, therefore, the marijuana intoxication "muffled" or "modified" the expected hostile response to a frustration stimulus. Our data, along with other clinical and research findings, suggest that marijuana intoxication is not associated with increased hostility. Furthermore, even under conditions that are expected to produce hostility, marijuana-intoxicated subjects feel less hostile and exhibit decreased negative verbal behavior (including sarcasm).

Nahas (17, p. 286) has suggested that hostile and violent behavior may occur during marijuana intoxication. Indeed, isolated cases of aggression and hostility were included in the LaGuardia report (5, pp. 269–274, 313–335, and 354–360). Halikas and associates (40) reported in interviews with marijuana users that 43% experienced occasional aggressive feelings and 37% reported feeling irritable. Kolansky and Moore (41) reported two cases of verbal aggression and sarcasm associated with chronic marijuana use. Thus, the literature regarding the lack of association between marijuana and hostility is not unanimous, and any hypothesis about the effect of marijuana on hostility must include the potential for an increase as well as a decrease. Furthermore, subjective reports of marijuana intoxication may differ from observable behavior. Our observations and those of Galanter and associates (28) illustrate the lack of correspondence between self-ratings of hostility and the ratings of nonintoxicated observers.

In order to reconcile the various observations regarding hostility and marijuana, we hypothesize a multidetermined relationship with the following components.

1. *Dose.* At low doses, marijuana may produce mild disinhibition of the type seen in our subjects after ingestion and before frustration. At higher doses, the intoxication may facilitate hostility in certain settings (42). Thus, Nahas comments, "overt aggressive behavior . . . requires the absorption of enough active material and also an unfavorable setting" (17, p. 286). Very high doses of marijuana may produce sufficient sedation to obscure any other effect (43).

2. *Environment.* The laboratory setting may have contributed to the observed decrements in marijuana-intoxicated subjects' hostility following a frustration stimulus. The subjects, feeling the challenge to improve upon their task performance, may have been able to increase their vigilance and attention enough to successfully complete the task. Weil and Zinberg (44) have reported the ability of mildly intoxicated experienced marijuana smokers to improve vigilance and performance when challenged by certain psychological test performances.

3. *Stimulus.* The frustration stimulus, while adequate to produce hostility in placebo subjects, may not have been strong enough to stimulate hostility in marijuana-intoxicated subjects. A stronger stimulus (e.g., a threat) in a less friendly environment might produce hostility, particularly with a larger dose of marijuana. The present research design (like many others) does

[1]Correlations were not compared for the placebo subjects because we thought that there was insufficient variance in this group to permit meaningful interpretation of a correlation.

not allow for extrapolation to a more hostile environment, such as a ghetto, or to a stronger stimulus, such as war.

4. *Subjects*. Factors within the individual subject, such as prior experience with marijuana and expectations about the experiment, may be of considerable relevance to the production of hostility. The range of available adaptive ego defenses may also be important. If, for example, the intoxicated subject has a well-developed, healthy (nonpathological) obsessional character style, then the challenge and dose of marijuana in our study might help to mobilize these defenses. Subjects may have used isolation of affect (particularly hostility), intellectualization about the experiment, and rationalization about the frustration stimulus to temporarily override the intoxication and complete the task. If these ego defenses control more serious psychopathology, however, then higher doses of marijuana in the presence of stronger stimuli and nonsupportive environments might lead to decompensation rather than disinhibition. Panic, psychosis, and concomitant aggressive behavior might result (45).

We hypothesize that the relationship between marijuana and hostility may be the collective result of an interaction between the drug and other factors. In our laboratory, the supportive group structure, modest dose, and mild frustration stimulus were not associated with increases in hostility. However, we suggest that the relationship between marijuana and hostility requires further exploration.

Prompt Publication Policy

The *Journal* would like to remind authors who are particularly interested in early publication (whether to establish priority of an idea, reveal innovative results of new research, or for other pressing reasons) of its prompt publication policy. Under this policy, short (maximum of six double-spaced pages) manuscripts will be considered for publication in the Brief Communications section of the first available issue. These manuscripts must still undergo expert scrutiny before being accepted, and two months must be allowed for the printing process. However, the time required for publication of these short articles can be lessened considerably.

Authors who would like to have their manuscripts considered under this policy should indicate this desire, as well as the reasons for it, when they submit their manuscripts.

The Treatment of Anorexia Nervosa

BY ALEXANDER R. LUCAS, M.D., JANE W. DUNCAN, M.D., AND VIOLET PIENS, R.N.

The authors report on their treatment of 32 young patients with severe anorexia nervosa who had lost an average of 37% of their original body weight. The therapeutic approach, conceived to meet both the physiological and the psychological needs of the patients, was carried out in a psychiatric unit for adolescents in a general hospital and involved separation of the patient from his or her family, treatment of the malnutrition, individually planned psychotherapy, and concurrent work with the family. The importance of accepting the patient's uniqueness, maintaining long-term contact, and encouraging the patient's striving toward constructive growth and autonomy is emphasized.

TREATMENT OF ANOREXIA NERVOSA has ranged from coercive feeding calculated to restore metabolic balance and normal weight to approaches that ignore the malnutrition and focus on the dynamic issues assumed to underlie the disturbance. Neither of the extreme approaches has been satisfactory, nor is anorexia nervosa a disorder that will remit spontaneously once its course has become established. The high mortality rate (up to 22%) (1, 2) attests to these facts.

We believe anorexia nervosa is a serious and potentially fatal disorder requiring prompt and specific intervention to treat its physiological and psychological components. In its advanced stages it constitutes a medical and psychiatric emergency. With appropriate treatment, a remission of all the symptoms, if not a permanent cure of the underlying tendencies, should be possible.

The extensive body of literature on anorexia nervosa has been documented in the monograph of Bliss and Branch (3) and in more recent reviews (1, 4). Between the extreme approaches to treatment lies a range of techniques with varying theoretical foundations and methods. Although many treatment approaches are advocated, until recently there has been a consensus that the treatment of anorexia nervosa is difficult and usually prolonged.

Behavior modification has been advocated because of its simplicity and the rapidity with which the treatment can produce weight gain. The coercive nature of the treatment described in some reports and the resulting rapid changes in body image should be cause for concern about the hazards of this form of treatment (5–7). Bruch (8) stated that true benefit is derived from weight gain only if it is integrated with correction of the underlying individual and family problems.

Bed confinement, forced feeding, and psychotropic medication constitute the treatment preferred in Great Britain (9, 10). Like behavior modification, this approach is fraught with risks. Tube feeding, aside from its symbolic meaning, carries the hazard of overhydrating the patient and thus excessively taxing the cardiovascular system. Berkman warned about the hazards of intravenous fluid administration years ago (11). He stressed the importance of three regular meals containing bulk and advocated a regimen designed to help patients regain mastery over their eating behavior.

When psychotherapy directed at uncovering unconscious motivation for self-starvation and removing the defenses against anxiety is the sole mode of treatment, the eating behavior will very likely remain unchanged or even worsen.

Successful treatment efforts (4, 11–16), despite their variation in specific techniques and differing underlying theoretical considerations, have several factors in common: 1) there is one primary therapist who exerts a strong influence over the patient or there is a close-knit treatment team who use a consistent approach and who are identified by the patient as a cohesive group; 2) there is genuine commitment to the patient, who is approached as a unique human being; 3) there is continuous long-term involvement with the patient; 4) there is understanding of both the physiological and psychological components of the disorder, and treatment ignores neither of these components; and 5) there is awareness of family and other environmental influences that help or hinder the patient's progress, and these influences are considered in the treatment plan.

Revised version of a paper presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

Dr. Lucas is Head of Section, Child and Adolescent Psychiatry, and Associate Professor of Psychiatry and Dr. Duncan is Consultant in Child and Adolescent Psychiatry and Assistant Professor of Psychiatry, Mayo Medical School, Rochester, Minn. Ms. Piens is Head Nurse, Residential Treatment Unit, Rochester Methodist Hospital, Rochester, Minn. Address reprint requests to Dr. Lucas at the Mayo Clinic, 200 First St., S.W., Rochester, Minn. 55901.

The authors gratefully acknowledge the contribution to the treatment of patients made by residents in psychiatry and child psychiatry and by the staff of the Residential Treatment Unit as well as the assistance of Veronica Blaha, R.N., in reviewing patient records.

This study will describe the treatment approach that we have evolved during the past 3 years on the basis of our training and our experience in treating patients with anorexia nervosa at the Mayo Clinic.

DIAGNOSTIC CRITERIA

Anorexia nervosa is a distinct psychosomatic entity that should be differentiated from other forms of psychogenic weight loss, as Bruch emphasized (4). She identified as central issues the struggles for self-respect, identity, control, confidence, and effectiveness. The criteria of Feighner and associates (17) are useful guides in defining a homogeneous patient group. The characteristically distorted attitude toward food and eating, with an overriding desire to maintain thinness, is perhaps the one clinical feature necessary for a diagnosis of anorexia nervosa. Setting absolute age and weight criteria is arbitrary; most often the illness begins around puberty or shortly after, between ages 10 and 20, but it may begin later. The later the symptoms begin, the greater is the likelihood that another illness, such as depression or schizophrenia, is primary. Feighner and associates used weight loss of at least 25% of the original body weight as a criterion for diagnosis in psychiatric research, but the diagnosis can and should be established before that degree of inanition is reached.

DESCRIPTION OF PATIENTS

Since October 1971, 32 patients with anorexia nervosa have been treated in the Mayo Clinic's Residential Treatment Unit (see table 1). Twenty-seven of the patients were girls, and 5 were boys. The age at admission for the girls ranged from 10 years, 5 months, to 21 years, 10 months, with a mean age of 17 years, 2 months. For the boys the age at admission ranged from 11 years, 7 months, to 16 years, 5 months, with a mean age of 13 years, 6 months.

The mean age at onset of illness for the 5 boys in our series was 12 years, 5 months. For the 27 girls it was 16 years (see figure 1). The duration of illness before admission ranged from 5 to 49 months, with a mean duration of 13.8 months. Weight loss averaged 19.9 kg (43.8 lbs), or 37% of the patients' original body weight. All patients had a distorted attitude toward food and eating and a desire to maintain thinness that overrode hunger and parental threats. All 27 girls were amenorrheic. Five were prepubertal or had delayed menarche, and 22 became amenorrheic as part of their illness. Overactivity was a prominent feature in 29 of the patients. Excessive exercising had been reported in the histories of most, but in others this activity became evident only after they were admitted. Bradycardia was observed in 11 patients. Episodes of bulimia were reported in 10 patients and vomiting in 14.

TREATMENT EXPERIENCE

General Principles

The treatment we will describe applies to cases of severe anorexia nervosa in which we judged hospitalization to be necessary. We have used a combined medical-psychiatric approach, with a carefully coordinated team effort dealing with both the inanition and the psychological conflicts. Our therapy has the four following facets:

1. Separation from the home to interrupt the power struggle between child and parents and to remove the child from an atmosphere emotionally charged on the issue of eating.
2. Treatment of the malnutrition. By taking responsibility for eating behavior and the decisions involved, we initially foster dependency on the therapist and the hospital, but we gradually encourage increasing autonomy for the patient in managing her or his own eating. The aim is for the patient to achieve a level of comfort in eating without excessive awareness of eating or counting calories before dismissal from the hospital.
3. Psychotherapy is focused on the individual. Initially supportive, it deals eventually with such issues as the expression of anger, control, ambivalence toward parents, and dependence and independence. Psychotherapy continues after the patient leaves the hospital but varies in frequency and intensity, as dictated by the patient's needs and reality factors.
4. Work with the family. This is essential if the patient is to return home; it may be more or less intense, ranging from supportive counseling about family interaction with the child to active treatment of the problems of other family members.

Treatment of the Malnutrition

Patients with anorexia initially eat in a separate dining room under the supervision of a nurse. A diet tray—calculated to maintain the admission weight—is served, with the expectation that the patient will eat everything. Periodically, as the patient is able to tolerate increased amounts, small caloric increments are added to achieve gradual weight gain. As few ward staff as possible are involved in the direct supervision of eating to avoid power struggles and the playing of one staff member against another. Crucial in the success of this approach are the skill and attitude of the nurse who supervises mealtime. The nurse needs to convey a sense of firmness and equanimity and must also be alert to attempts at deception and manipulation. He or she must be patient, compassionate, and unruffled by the patient's emotional outbursts. As progress is made, the patient moves to the regular dining room, where she or he serves herself or himself under gradually diminishing staff surveillance.

Psychotherapy

The psychiatrist directs the medical regime and conducts the psychotherapeutic discussions of the treatment process. The initial interviews set the themes for

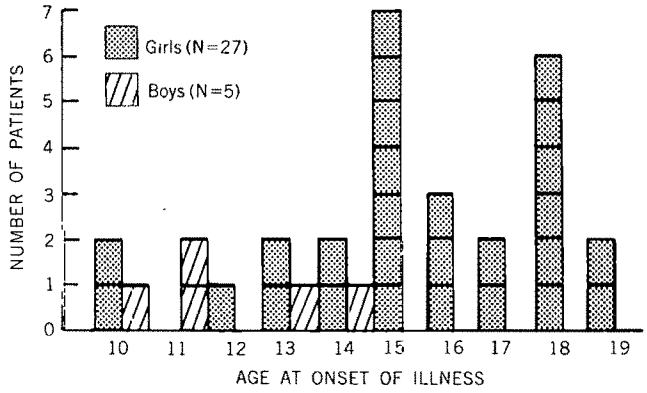
* These patients were discharged against medical advice.

subsequent therapy. Therapist and patient can acknowledge that dieting and its resultant malnutrition have become severely destructive and are out of control. The patient wants and needs help to stop losing weight and, gradually, to learn to eat in accordance with nutritional needs instead of fears.

The psychiatrist explains that he or she will prescribe a diet designed only to stabilize the patient's present weight and to avoid the discomfort associated with food intake and transient fluid retention insofar as is possible. Periodically, the psychiatrist will prescribe small increases in the calories and bulk in the patient's diet, but only in conjunction with monitoring of the patient's physical and emotional condition. The patient is assured that the treatment plan will be as flexible as her or his needs may dictate. In brief, the patient is asked to relinquish control of decisions pertaining to eating and to accept the necessary staff monitoring of food and fluid intake and activity.



The psychiatrist tells the patient that later she or he may select a target weight within a range considered medically safe that she or he will achieve and maintain before leaving the hospital. This target weight will be achieved in steps, and each step will be associated with less of a need to monitor indices of clinical condition and therefore increased opportunity for the patient to direct her or his affairs in regard to eating and other aspects of life. She or he may learn to enjoy eating in accord with nutritional needs without external control of eating behavior.

Finally the psychiatrist notes that his or her values regarding weight and physical appearance may not be in accord with the patient's but that he or she will not impose his or her beliefs on the patient except that he or she will not permit the patient to starve or to become fat.

The objective of the initial interviews is to stabilize the patient at her or his own weight and level of functioning, permitting the patient to marshal defenses to cope with anxiety.

In our experience, as in that of others (12, 18), the patient's symptoms of apathy, social distance, mental fatigue, and shallow or inappropriate affect may reflect only physical starvation and psychological helplessness. They are therefore not targets for therapeutic intervention. Rather, discussions of the medical re-

FIGURE 1
Age at Onset of Illness of 32 Patients with Anorexia Nervosa

gime define for the patient a circumscribed and temporary dependency on the therapist, minimizing the anxiety associated with threats to autonomy.

Continuing Psychotherapy

The therapist continues dynamic management of the patient's autonomy and level of regression in continued discussions of the themes meticulously defined in the early sessions. The therapist freely uses data from staff observations of the patient in interactions with staff and with peers. In accord with the principles of psychotherapy with adolescents, psychic synthesis rather than analysis of defenses is sought (19). Only the defense mechanisms of denial and projection are interpreted because these seriously interfere with the patient's appreciation of reality (20).

Revision of body image. The therapist selectively focuses on data that pertain to the discrepancy between the patient's body image and her or his body configuration (21). This discrepancy, with its associated defective perception of reality, is approached indirectly in terms of understanding changes that occur in body structure and function as treatment progresses. The therapist is assisted by the patient's relatively realistic perception of the body configuration of other emaciated patients and by reflecting on comments made by nonanorectic peers. The patient's gradual delineation of a body image more consistent with her or his body structure is manifested in the therapy sessions.

Revision of body concept. Revision of body concept to include recognition of internal body sensations is a formidable therapeutic task. It is approached indirectly by the therapist's fostering the patient's awareness that healthier peers use hunger or satiety signals to guide realistic eating behavior. Data concerning the patient's difficulty in recognizing sensations and differentiating these feelings from emotions come under therapeutic investigation.

Milieu therapy. A residential adolescent treatment unit provides many models for imitation and identification. Additionally, in the natural course of events various interpersonal conflicts arise. All aspects of the patient's functioning are suitable data for therapeutic discussion. The patient's interactions with other anorectic patients are especially enlightening because the patient may see in them a repetition of earlier relationships with the mother.

Termination of hospital treatment. When the patient is ready to leave the hospital, psychotherapy is usually at a point where topics other than eating—the patient's relationships with peers and with parents, the expression of anger, the issues of self-assertiveness and independence—are being dealt with. In therapy and on the ward, the patient has experimented with and has learned to master more effective ways of dealing with others. We look for spontaneity in behavior and a return of the patient's sense of humor as signs of recovery. Continued follow-up is essential because treatment is usually not completed at discharge.

RESULTS

Patients remained in the hospital up to 11 months; the usual stay was between 3 and 5 months. Those who weighed the least at the time of hospital admission required a longer time to attain a weight adequate to warrant transition to outpatient care. Three patients left against medical advice after less than 1 month of treatment. Each patient's weight gain achieved in the hospital is recorded in table 1, where it can be compared with the previous weight history and duration of hospitalization. Clearly, each patient gained weight. The secondary symptoms of apathy, mental fatigue, and depression diminished gradually as weight gain was achieved. Increased spontaneity in relationships with peers and adults and freedom to express feelings candidly usually occurred.

The test of the effectiveness of treatment rests not in the statistics of weight gain but in the patients' ability to master eating behavior, as demonstrated by maintenance of both physical health and psychological integrity after treatment. A follow-up study of these patients, assessing personal, social, and academic adjustment, is in process. Although the great majority of the patients maintained substantial weight gains and made improvements in their general adjustment for periods of up to 3 years after discharge we believe it is too early to draw definitive conclusions about the success or failure of treatment.

CONCLUSIONS

We believe that the treatment of anorexia nervosa requires a humane approach in which the patient is accepted as a unique individual. Treatment should be predicated on a sense of optimism and on a conviction that the patient wants to get well. Both the physiological and psychological needs of the patient must be met in a treatment situation in which the therapist allies himself with the patient's healthy defenses and desire for constructive growth and autonomy.

Neuropsychological and EEG Disturbances in Polydrug Users

BY IGOR GRANT, M.D., AND LEWIS L. JUDD, M.D.

EEG and neuropsychological evaluation of 66 polydrug users revealed that 43% had EEG abnormalities and 45% had neuropsychological impairment 3 weeks after admission to a polydrug study unit. At 5-month follow-up, 27% of 30 retested subjects were still impaired neuropsychologically. Impairment may be related to extensive involvement with sedatives, alcohol, or heavy polydrug use. The authors suggest that cerebral dysfunction in polydrug users might be the result of organicity of intermediate duration and that deficits may be experienced by some beyond 5 months of reduced use or abstinence. Organicity may dictate structured, reality-based intervention techniques, especially early in treatment.

THE CONTINUED ABUSE of psychoactive drugs by a significant minority of our population has raised the possibility that at least some users might suffer consequent brain damage. Although there has been much speculation, carefully conducted studies have been few, and the results have been contradictory. For example, the suggestions by Kolansky and Moore (1, 2) and Campbell and associates (3) that marijuana might cause brain damage have not been supported by the work of Mendelson and Meyer (4), Rubin and Comitas (5), Grant and associates (6), or Culver and King (7). Similarly, although adequate methods to assess cerebral function were used, five neuropsychological investigations of LSD users yielded contradictory results (8–12). Perhaps our best information so far relates to alcohol, which is clearly associated with cerebral dysfunction in at least some continual users (13–17).

The lack of objective information regarding the long-term effects of chronic abuse of barbiturates and nonbarbiturate sedative drugs on brain function is particularly striking since the abuse of such substances is a serious and growing problem (18, 19). We have been engaged in a comprehensive longitudinal study of "polydrug" abusers whose primary modal pattern of drug abuse is with central nervous system depressant drugs. In this paper, we will describe the preliminary results of the neuropsychological and electroencephalographic assessments in a sample of 66 polydrug abusers; these results represent one aspect of information being gathered on more than 120 subjects over a 2-year period as a part of a comprehensive polydrug treatment demonstration project sponsored by the National Institute on Drug Abuse.

METHOD

The first subjects admitted to the project were 36 men and 30 women ranging in age from 14 to 54 years (mean=26.3±8.5) and in education from 7 to 16 years (mean=11.8±2.2). Written statements of informed consent were obtained from all subjects after the details of the experiment had been carefully explained to each subject individually. The drug experience of the subjects is summarized in table 1. Since most of our subjects reported using virtually every type of drug at some time during their lives, the figures in table 1 represent heavy use only. For our purposes, "heavy use" is defined as the equivalent of daily experience with a substance for 1 year or more, except for hallucinogens and volatiles, where 100 or more total experiences constituted heavy use. The most frequent substances of abuse (used by 79% of the subjects) were drugs of the sedative-hypnotic class, including barbiturates, nonbarbiturate hypnotics, and minor tranquilizers (meprobamate, chlordiazepoxide, and diazepam). Fifty percent of the subjects were heavy users of stimulant drugs (amphetamines), and over 50% reported heavy and prolonged experience with three or more substances; these percentages indicate that this was a truly polydrug-abusing group.

At the time of their admission to the Polydrug Study Unit, an ambulatory facility in the downtown San Diego area, all subjects underwent an initial set of assessments, which included the gathering of a personal history, drug use information, medical history, a physical examination, and routine laboratory studies, including blood and urine toxicology. Most subjects continued as outpatients, although a few (less than 10%) were admitted to an inpatient unit for detoxification from sedative dependence. To allow acute drug effects

and effects of possible abstinence phenomena to clear, 3 weeks elapsed before the subjects received a comprehensive neuropsychological evaluation and EEG. Repeat EEG and neuropsychological testing were performed 5 months later.

The neuropsychological examination consisted of the battery of tests assembled by Reitan (20), which includes seven Halstead tests, the Wechsler Adult Intelligence Scale (WAIS), the trail making test, an aphasia screening test, a sensory perception examination, a lateral dominance examination, measurement of strength of grip, and the MMPI. The testing took 4–5 hours, and the results were analyzed both actuarially (psychometrically) and clinically. The EEG was performed on the same day or within 24 hours of neuropsychological assessment. Routine montage was employed, and the examination included periods of activation by hyperventilation and photic stimulation. The results were scored clinically by an electroencephalographer using the Mayo system (21) and were also recorded on magnetic tape from which a computerized, compressed spectral array could be plotted.

RESULTS

Initial Testing

The initial neuropsychological test protocols for each of the 66 subjects were evaluated by a clinician experienced in neuropsychological assessment (I.G.).[1] Of the 66 protocols, 30 (45%) were judged on clinical grounds to be neuropsychologically impaired. The majority of the protocols classified as abnormal were judged to be mildly to moderately so, with evidence of generalized, nonlateralized cerebral disturbance. General areas of deficit included difficulties in abstracting ability and problems in perceptual-motor tasks. Interestingly, general intelligence, memory, and verbal skills were not found to be abnormal in most of the subjects. EEGs were completed on 60 of the subjects. All EEG records were reviewed by an experienced electroencephalographer (Reginald Bickford, M.D.), and 26 (43%) were judged to be abnormal. According to the Mayo scoring system, 60% of the abnormal EEG records were classified as dysrhythmia I and 35% as dysrhythmia II. Other specific EEG abnormalities included excessive slowing in 50% of the subjects, with 3- to 4-cps or 6- to 7-cps bursts, spikes or spike wave complexes in 35%, and excessive fast activity in 12%.

There was a 75% agreement rate between the independently rated neuropsychological protocols and EEG results for the 60 subjects. Twenty-six individuals were rated normal and 19 were rated abnormal by both methods of inference. Disagreements occurred in 15 cases (25%); 7 individuals were regarded abnormal by the electroencephalographer and normal by the neuropsychology rater, and 8 individuals were judged to be neuropsychologically abnormal but normal on the EEG. These results indicate that the rate of cerebral dysfunction among polydrug users 3 weeks after admission ranges from 32% to 57%, depending on whether one or both methods of assessment are employed in making the diagnosis.

Neuropsychologically impaired subjects did not differ from unimpaired subjects in regard to age, sex distribution, education, or medical history. In particular, history of head injury did not separate the two groups. A comparison of the drug use experience of subjects judged to be normal and abnormal on both EEG and neuropsychological grounds showed an association between dysfunction and the following types of drug use: heavy CNS depressant use ($\chi^2=6.55$, $p<.02$); heavy alcohol use ($\chi^2=4.07$, $p<.05$); and heavy use of four or more psychoactive substances ($\chi^2=5.55$, $p<.02$).

Assays for serum levels of sedatives, narcotics, and amphetamines are available for 43 of the 66 subjects. Of the 12 subjects who had measurable amounts of barbiturates in their blood, 6 were judged to have neuropsychological deficits (serum barbiturate=0.5–3.3 mg/100 ml) and 6 were unimpaired (serum barbiturate=0.1–.3 mg/100 ml). Of the subjects with no detectable drugs in their blood, 12 were classed as impaired and 19 as normal.

Follow-Up

When repeat neuropsychological evaluations were completed at 5 months on 30 of the original 66 subjects (45%), 8 subjects (27%) were judged to have evidence of cerebral deficits; 7 of these 8 subjects had also been judged to be impaired at initial testing. One woman who had an intercurrent head injury was initially tested as unimpaired and, understandably, was impaired at retest.

EEG information is available on 20 of the 30 follow-up subjects. The neuropsychologist and the electroen-

[1]Dr. Grant received training in the neuropsychological laboratory of Ralph Reitan, Ph.D. They established an agreement rate of 80% in independent clinical ratings of neuropsychological protocols as part of a previous study (21).

cephalographer agreed in 17 cases (85%), and disagreed in 3 cases (15%). Thirteen subjects were normal both on EEG and neuropsychological examination. Thus, the rate of cerebral dysfunction at follow-up in the 20 patients who had both EEG and neuropsychological assessments ranges from 20% to 35%, depending on strictness of diagnostic criteria. The follow-up sample size is, at this point, too small to discern any possible interactions between drug use history and persistent cerebral dysfunction. In general, individuals reported considerably less involvement in drug abuse at 5-month follow-up than at time of admission. For example, 60 of the 66 initial subjects (91%) were judged to be heavy users of at least one substance when they enrolled in the program. At follow-up, 13 of the 30 returning subjects (43%) were classified as heavy users. There does not appear to be a causal association between interim or acute drug use and continued evidence of impairment. Twenty-four of the subjects (including all 8 individuals with neuropsychological deficit) had blood toxicological screening on the day of retest, and no measurable amounts of barbiturates, amphetamines, or narcotics were found in any subject.

The reasons, in order of importance, that 36 of the original 66 subjects were not retested were refusal to participate in follow-up retest, relocation out of state, and incarceration in jail. Two individuals committed suicide (3% of the initial sample). The subjects who were not retested do not appear to differ from those who were on the basis of age, sex, education, history of drug abuse, and initial neuropsychological status.

DISCUSSION

The subject sample was evenly divided between men and women and represents a wide range in ages and educational experience. In general, the group appeared to be a very representative sample of drug abusers in whom drug use played a highly significant role in all aspects of their social and psychological functioning. The group's drug use history is impressive—even with rather stringent criteria for defining heavy use (i.e., daily experience for a year or more), the majority of the subjects were so classified. The great majority abused CNS depressant drugs, and a significant portion of the sample reported heavy use of three or more drugs.

A surprisingly large number of subjects had abnormalities significant enough on their neuropsychological and EEG protocols (45% and 43% of the subjects, respectively) to be suggestive of a cerebral dysfunction 3 weeks after admission to the project. The rates of neuropsychological impairment were considerably higher than those we have observed among age- and education-matched medical patient nondrug users (11% to 26%) (22) and exceed the usually quoted EEG abnormality figures for the general population (10%) (23, 24). The high level of agreement between the neuropsychological evaluation and the EEG results is encouraging and adds further validity to the presence of cerebral dysfunction since the abnormalities were manifested in both of these independent assessment procedures.

The study design was not prospective in nature, and therefore we do not have baseline neuropsychological or EEG studies on individuals before their drug use. We can only speculate on what portion of these individuals would have been judged to be abnormal regardless of intercurrent drug use. Thus, one can only generalize about the relationship between heavy drug use and cerebral deficits. Nevertheless, aspects of the data give some indication that there may be a relationship between heavy drug use and presence of these abnormalities on neurological assessment. Neuropsychological impairment among our subjects was not related to age or education, but there was an interaction with three drug-use conditions (heavy alcohol use, heavy sedative use, and heavy use of four or more drugs). In addition, the types of deficits noted correspond remarkably to the impaired abstracting ability and visual-spatial integration disturbances reported by Fitzhugh and associates (13, 14), Goldstein and Shelly (15), and Jones and Parsons (16, 17) in their studies of chronic alcoholics. It would be inappropriate to infer from these preliminary observations that chronic sedative users develop brain disorders similar to those of alcoholics. Nevertheless, the neuropsychopharmacological similarity of the sedative drugs to alcohol, coupled with the finding of similar cerebral deficits, suggests that the question of long-term neurotoxicity of sedatives demands active exploration.

Another factor in interpreting the data in this subject sample is whether or not the results were altered by the effects of acute drug intoxication. In order to control for this, all subjects were clinically screened before the neuropsychological and EEG procedures. It soon became clear that the empirical evidence of intoxication in a chronic user was much less demonstrable than we had anticipated. At this point, a blood and urine toxicology screen was initiated as an objective measure of whether or not the subject was under the influence of any drug. Six subjects had what would be considered clinically significant serum barbiturate levels, and all 6 were judged to have neuropsychological deficits. Therefore, it is most likely that the neuropsychological deficits in these 6 individuals are more directly related to the effects of acute ingestion than to any chronic cerebral dysfunction. Of the 37 subjects who had only trace amounts of barbiturates (N=6) or had no detectable barbiturate levels in their serum (N=31), 12 had neuropsychological protocols that were judged to be definitely impaired.

Although acute drug effects were not operating in these 37 individuals, the deficits might still be the result of organicity of intermediate duration caused by abstinence from alcohol or sedative drugs. Indeed, this is the most likely explanation for the drop from 46% neuropsychological impairment at initial testing to

27% at 5-month retest. Of more interest is the fact that, with the exception of an individual who suffered a head injury between testings, all subjects who appeared impaired at retest were also abnormal initially. Our interview data failed to reveal any differences in intercurrent drug or alcohol use between the subjects who improved and those who did not; this may indicate that certain cognitive deficits may be more persistent or chronic in nature. An 8-month follow-up currently in progress should help distinguish intermediate-length, slowly reversible effects from permanent cognitive impairment. As follow-up data continue to accumulate, we believe that enough objective information will be available to make a more definitive statement regarding long-term CNS effects of heavy polydrug involvement.

CONCLUSIONS

The fact that few cerebral deficits were demonstrated by the standard adult intelligence scale is an indication that these changes are not obvious and require a rather sensitive assessment procedure. It appears from this study that EEG and the neuropsychological battery assembled by Reitan are mutually enhancing and may, in combination, add considerable sensitivity and sureness to the identification of subtle cerebral deficits, an area that has long been a diagnostic problem. The fact that almost half of our polydrug users could be classified as "organic" during their early weeks in treatment may explain some of the inattention, distractibility, unreliability, lack of motivation, and "denseness" so often described and so frustrating to therapists. This finding also suggests that a very clear, more simply structured, reality-based intervention might be the treatment of choice and have the potential to reduce the proneness to treatment failure so often seen with polydrug abusers.

A Description and Evaluation of an Outpatient Intensive Psychotherapy Center

BY WENDELL M. SWENSON, PH.D., AND HAROLD R. MARTIN, M.D.

The intensive psychotherapy center described and evaluated in this paper is unique because of its intensity and the fact that available treatment modalities are integrated into the program. Patients are literally immersed in therapy on a full-time basis for an average of 3 weeks. Assessment of the program through the use of questionnaires completed by 335 patients at the time of discharge showed significant improvement in their presenting symptoms, interpersonal relationships, ability to work, and general level of comfort. An 8-month follow-up study of 171 patients revealed that this improvement was retained.

SHORT-TERM INTENSIVE outpatient psychotherapy has been increasingly considered the treatment of choice for many psychoneurotic conditions and problems of interpersonal relationships in recent years. This is apparent in changes in some of the more traditional treatment programs (1, 2).

Nearly 8 years ago the Department of Psychiatry and Psychology of the Mayo Clinic developed a program of short-term intensive outpatient psychotherapy that has evolved pragmatically into the program we will describe and evaluate in this paper.

DESCRIPTION OF PROGRAM

The Mayo Clinic program is unique, not primarily because it contains new psychotherapeutic techniques, but because of its intensity and the manner in which available therapeutic modalities are interwoven. The patients selected for treatment at the Intensive Psychotherapy Center (IPC) represent a broad spectrum of neuroses, personality disorders, and psychophysiological disorders. Most come to the clinic just as they would consult a general physician or another medical institution, i.e., for problems that are later found to be psychoneuroses or difficulties in interpersonal relationships. Treatment at the IPC is a full-time experience 5 days a week for 2 to 5 weeks (average, 3 weeks).

The therapeutic techniques integrated into this program include group psychotherapy, examination of videotaped group interaction facilitated by an "objective" or uninvolved observer, individual psychotherapy, psychodrama and other encounter techniques, activity therapy, and a form of conjoint family therapy that usually involves the patient's spouse.

These several treatment modalities and therapeutic approaches are integrated and interrelated primarily through the manner in which the clinic personnel are used. A psychiatric resident and a cotherapist (usually of the opposite sex), as a team, constitute the patient's therapists. They are involved in or responsible for each patient's daily therapeutic experiences. The treatment unit has basically the same patient-therapist composition during the entire treatment period and comprises the patient's "home group," even though the patient may be temporarily involved in other experiences (e.g., encounter groups or activity therapy). The total program includes three treatment teams. In this varied but cohesive treatment milieu, a typical day at the center is characterized by constant feedback, exchange of opinions, and discussion of the dynamics of the day's therapeutic experiences. Through this design, therapeutic content dealt with in any one session in a given day is automatically funneled into the other sessions of that day.

On arrival at the IPC a new patient is assigned to one of the three treatment teams; he or she thus joins an established home group. Each group contains 7 to 8 patients. The heterogeneity of the patient groups is guaranteed because the only conditions for admission are the consulting psychiatrist's impression that the patient has met previously identified diagnostic criteria and that he or she might benefit from short-term intensive psychotherapy. This heterogeneity was confirmed by data after 1 year of operation showing that the age of patients ranged from 18 to 66 years (modal age group, 30 to 40 years). About 45% of the patients were men, and 55% were women. Educational levels ranged from less than eighth grade to postgraduate or professional degrees. Socioeconomic levels were commensurate with educational achievement.

A typical day for one group of patients illustrates the

character of the program (see group 1, table 1). At 8:00 a.m. a staff meeting is held during which administrative problems are dealt with, clinical issues are discussed, and any new patients coming to the center are greeted briefly. At 9:00 a.m. the home group meets with its therapist and cotherapist for the first group therapy session. At 10:00 a.m. there is a videotape replay of the preceding hour's group psychotherapy with an objective analysis of the group interactions by a previously uninvolved member of the staff. During this hour the primary therapist and cotherapist of the group meet with the supervising psychiatrist for a review of their observations of the session. At 11:00 a.m. half of the patients meet for psychodrama or other encounter groups. (Members of other groups may be included.) At noon, all of the patients in the IPC have lunch together. At 1:00 p.m. a second group therapy session is scheduled with the home group. From 2:00 p.m. to 3:00 p.m. the patients are available for individual psychotherapy, traditional activity therapy, or videotape replay of the psychodrama. From 3:00 p.m. to 3:30 p.m. the entire patient population from the three groups meets with the three resident psychiatrists and the three cotherapists for a "summary group" to go over the day's encounters.

All of the group sessions are recorded on audiotape; these are frequently used by the patients during the activity therapy periods to reexamine the past hour. Other techniques such as "mini-marathons" (5 hours) are occasionally used when the therapists feel the group may benefit from such an approach.

An important characteristic of the program is the frequent use of conjoint therapy in which a spouse or other relative is included in the total program. We have found that this is frequently crucial even when overt marital problems are not initially apparent.

CASE REPORTS

The following examples are presented to illustrate the manner in which material from one treatment modality feeds into another and how the differing treatment approaches supplement and complement each other to produce continuity that ties the treatment program together.

Case 1. A 40-year-old attorney attended the IPC with his wife. She and others in the group recognized that his passive-dependent "fatherly" relationships with women were actually a means of seductive manipulation, although he remained unconvinced. In psychodrama, a conflict situation was constructed in which he had to deal with two attractive young women. Feedback from the patient group and his coparticipants in the drama and the videotape allowed him to see clearly for the first time his pattern of seduction. After this he was able to examine his relationship with women generally, including his daughters, and two earlier extramarital affairs in which he had seen himself as a "victim of circumstances."

Case 2. A 20-year-old hostile-dependent woman had worked through the dynamics of many of the neurotic symptoms that had brought her to the IPC. However, it was only when she saw herself isolated in the sociograms of one of the encounter sessions that she recognized the distance between her and the other group members and began to feel her own loneliness. She was able to ask for and received feedback from the other patients regarding the anger and condescension they felt she projected in spite of her superficial mask of warmth and caring. Although she reacted very little at the time, her cotherapist found her crying later in the day. She then revealed her anger and hurt and went on to abreact her relationship with her father. This reaction continued into the summary group, in which she related this smoldering anger and her defensive manner toward people in general. The following morning she was able to continue her therapy on a deeper plane.

EVALUATION

Two of the most difficult problems in psychiatry are evaluation of results and comparison of treatment methods. To quantify such abstract phenomena as anxiety, tension, depression, maladaptive behavior, interpersonal conflicts, or pain from tension is often considered to be a virtually impossible task. Nevertheless, it is important that an attempt be made to measure results in as objective and quantified a manner as possible.

To determine the effectiveness of the IPC, we developed a questionnaire to obtain information regarding behavioral and attitudinal changes of patients attributable to this experience. This questionnaire and certain standard psychometric devices (the MMPI, the Adjective Check List [3], and the Shipley-Institute of Living Scale for Measuring Intellectual Impairment [4]) were administered routinely to 315 patients admitted to the IPC. The patients were also evaluated by means of standardized questionnaires completed by the psychiatric resident and the cotherapist on admission and discharge. (Results of these analyses will be published later.)

On admission the patients identified their primary, secondary, and tertiary symptoms (see table 2). (Fifty patients entered the IPC with their spouses at the latter's request and saw themselves as having no symptoms.) The patients filled out a second form of the questionnaire upon completion of therapy.

Approximately 8 months after discharge from the IPC, the patients were mailed a third form of the questionnaire to determine once again any change in their symptoms or their disability. Of the 315 patients in the study, 171 cooperated in this follow-up.

Table 3 contains data demonstrating the self-assessed status of the patients at admission and discharge. At the time of discharge there were no large

differences between patients who subsequently completed the follow-up questionnaire and those who did not. The modal change for all patients seemed to be moderate improvement (95 patients, 35.8%). However, in the total group and in each subgroup, more than 40% admitted substantial improvement or total absence of their primary complaint. On the other hand, 15% felt they had deteriorated or experienced no improvement. For the 146 patients who stated that they had an initial symptom and completed the follow-up questionnaire, treatment had some lasting effect for at least 8 months. Of these patients, 50% indicated that their complaint had either totally disappeared or continued to show substantial improvement. About 19% felt they had deteriorated or made no improvement.

All of the patients also rated their general feelings of discomfort, problems of interpersonal relationships, and ability to work efficiently (see table 4). In general, considerable improvement occurred in each of the three categories of functioning. At the time of discharge the patients were experiencing less general discomfort, were having less difficulty in interpersonal relationships, and were feeling better able to engage in their work. These results are statistically significant (two-tailed t test, $p < .01$). There were no significant differences between the group of patients who answered the 8-month follow-up questionnaire and those who did not.

CONCLUSIONS

A treatment program in which a broad spectrum of patients with psychoneuroses and personality disorders were literally immersed in therapy on a full-time basis 5 days a week for 2 to 5 weeks resulted in relief of presenting symptoms and of general discomfort and improvement in the ability to work and effectiveness in interpersonal relationships in a significant percentage of patients. An 8-month follow-up revealed that some patients had retained their level of improvement, others had partially relapsed, and others had continued to improve; therefore, as a group they had essentially retained the level of improvement that they had shown at the time of discharge.

It is our opinion that the key factors in the success of this program are, first, its intensity and, second, the manner in which several differing psychotherapeutic modalities and techniques are interwoven.

Quality-of-Care Standards and Professional Norms

BY HERBERT C. SCHULBERG, PH.D.

Incursions upon professional prerogatives are increasing with the advent of new requirements for accountability; this has stemmed in part from the government's enlarged role in paying for mental health services. The author discusses the effect of professional norms on the assessment of quality of care, including the concepts of risk and autonomy, observability and privacy, the perspective of time, and the appropriateness of the penalty. He offers some suggestions for the design and implementation of quality-of-care standards that he believes will benefit both professionals and administrators, as well as protect the patient.

THE CLINICAL PRACTICES of most psychiatrists have been directly or indirectly affected by increased requirements for accountability. Limitations on hospitalizing nondangerous patients have resulted from the Supreme Court's decision in *O'Connor v. Donaldson*, standards of treatment were altered by the *Wyatt v. Stickney* judicial decision, and time-limited outpatient care is often necessitated by the benefit structure of health insurance plans. Thus decisions about who is to be treated, with what methods, and for how long—which have traditionally been professional decisions—are now within the purview of nonprofessional control agents.

Incursions upon professional prerogatives are escalating. Citizen efforts to assure quality care tend to reject the premise that physicians are fundamentally humanitarian helpers who do no harm. The present crisis vis-à-vis medical malpractice insurance bears out the power of consumer interests. Third-party payers also have the power to influence service and its quality. It was reported recently that a major insurance carrier had sought a cutback in psychiatric benefits not only because of rising costs but also out of a concern for the relative lack of scientific rigor in regard to psychiatric diagnostic and treatment decisions (1).

Finally,and perhaps most significantly, there are pressures for quality control stemming from the government's enlarged role in paying for mental health services. The government requires disclosure of the purposes of expenditures and audits those expenditures to determine what the results have been; the same principle is now being applied to psychiatric programs. Although Professional Standards Review Organizations (PSROs) are currently limited to reviewing inpatient services, Goldstein and Cohen (2) speculated that their authority will be extended to other essential services as well.

Instead of assuming the initiative, mental health professionals generally respond in a reactive way to pressures for greater quality control. More stringent standards are usually adopted only after dubious practices evoke adverse publicity. For example, complaints by patients and their families were at least as forceful as professional distress in leading the Massachusetts Department of Mental Health to organize the Task Force to Study and Recommend Standards for the Administration of Electro-Convulsive Therapy (3).

The growing use of bureaucratically administered standards to assure the quality of psychiatric care conflicts in many ways with findings in the sociological literature that the professional's work suffers when detailed directives are passed down by administra-

Revised version of a paper presented at the Multiversity Conference on Quality of Treatment and Care, Greensboro, N.C., September 11, 1975.

When this work was done, Dr. Schulberg was Associate Executive Vice-President, United Community Planning Corporation, Boston, Mass. He is now Professor of Clinical Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, Pa. 15261.

The papers in this section are grouped around a specific topic. Publication here does not, however, imply that the Editor considers this material to constitute a comprehensive analysis of the topic.

tors (4). Individuals unable to control their work tasks are frequently found to be less satisfied with their jobs than persons who possess this power. Professionals have been viewed as functioning best in a "company of equals," which enables them to pursue organizational goals within a framework of ethics and controls learned from and shared with colleagues.

Why is this sociopsychological perspective on the optimal professional work environment being increasingly ignored? There are several possible reasons. Admirable as the sociopychological perspective may be, it fails to reconcile the continuing tensions among organizational values, goals, and professional work styles. For example, hospital administrators structure clinical services so as to maintain a balanced organization, but clinicians frequently plead for exceptions to rules in treating the patients for whom they are responsible. Similarly, the administrator's value system legitimates cost-benefit analysis and emphasizes fiscal solvency. Clinicians, on the other hand, often disdain cost-benefit considerations and cite the humanitarian value of psychiatric care regardless of its cost.

Within a framework of competing values, goals, and needs, quality control through the setting of standards can be viewed as the imposition of subjective values in the guise of pseudoscientific knowledge (5). Alternatively, standard setting can be seen as an effort to reconcile finite resources and infinite objectives (6). Since the resolution often involves compromise—settling for the immediately achievable rather than holding out for distant ideals—adopted standards may leave both psychiatrists and consumers dissatisfied.

Quality-of-care standards are also important to administrators who use them as control mechanisms in coordinating diverse staff behaviors (7). Procedures for controlling psychiatrists can be designed in various forms, some explicit and others implicit, some based on rewards and others on punitive measures. The use of explicit evaluation procedures based upon empirical standards is a growing trend, and if it continues, direct observation of patient care practices rather than assumptions based upon clinical reports will determine the psychiatrist's rewards and penalties.

CATEGORIES OF EVALUATION

As the mental health field is being forced to specify quality-of-care standards, it is struggling to refine appropriate evaluative criteria. Schulberg and associates (8) have emphasized that the choices depend upon many variables, including the specificity of an organization's goals and the feasibility of measuring them. Mental health centers often have nebulous goals and problematic assessment procedures. Consequently they evaluate organizational effort rather than patient outcome. Quantifiable indices of staff activity are readily established and include: 1) volume of service, 2) time per service, 3) cost per service, 4) administrative controls, and 5) professional qualifications. Any one (or a combination) of these indices can become a standard to be emphasized in utilization review and/or medical audit.

Specific standards usually are negotiated by the parties concerned in relation to the particular interests and needs of each. Outcome studies to determine whether patients have actually benefited from psychiatric efforts have been few, since measurable criteria are lacking. Thus in designing evaluations administrators and clinicians emphasize staff activities; indices of benefits to the patient are more difficult to design and usually are ignored in setting standards.

The clinical checklists and criteria developed by the Yale Psychiatric Utilization Review and Evaluation Project (9) for evaluating patient care are examples of the types needed in the psychiatric field. Using systems concepts, the Yale project sought to include structural, process, and outcome approaches in the review of patient care. The systems perspective is incorporated within checklists utilized 1) for the review of treatment provided suicidal patients, 2) in outcome studies with schizophrenic patients, and 3) in reviewing consultation activities.

Regardless of whether standards simply measure professional activity or in a more complex way assess patient outcome, psychiatrists generally prefer that standards be derived empirically through a continuous survey of local practice. Normative standards established by experts at the national level or by governmental bodies are less acceptable, particularly if they emphasize nonclinical concerns. However, the psychiatric leadership is seeking to bridge gaps between empirical and normative standards of care. The American Psychiatric Association has distributed guidelines for quality of care (10) that can be modified locally by the PSROs responsible for establishing standards applicable to their own areas.

Patient care can be assessed in relation to standards prospectively, concurrently, or retrospectively. Not surprisingly, prospective utilization reviews are most commonly performed with professionals in training, while experienced professionals find them most repugnant. It must be emphasized that evaluating psychiatric effort (prospectively, concurrently, or retrospectively) on the basis of standards rests upon the premise that prescribed levels of clinical activity produce beneficial outcomes. To the degree that this premise is untested or untenable, conformance to standards is meaningless and even misleading.

PROFESSIONAL NORMS

Since standards increasingly determine the assessment of quality of care, it is important to consider how professional norms either reinforce or resist this development. Norms represent guidelines by which practitioners determine the range of behavior appropriate and applicable to particular situations (11). When a new standard conflicts with long-established norms,

psychiatrists are challenged by both its pragmatic and symbolic implications. Pragmatically, a new standard may upset the clinician's customary work habits; symbolically, it can violate his/her self-image and sense of personal power over daily activities. It is not surprising, then, that the most controversial standards are those which clash with professional norms.

The psychiatrist's norm for evaluating clinical practice has traditionally legitimated assessment procedures that have been professionally devised and controlled. For example, ethics committee members monitor the practice of fellow psychiatrists and impose sanctions when indicated. They utilize clinical criteria rather than nonclinical criteria such as monetary costs in arriving at judgments, and they shield their findings from the scrutiny of administrators and clients, often giving as the reason the need to protect patient confidentiality. The remainder of this paper will consider these and other elements of the normative system that have long guided psychiatric practice in relation to quality-of-care assessment on the basis of newly emerging standards.

Risk and Autonomy

The professional's conception of the appropriateness of clinical practice stems primarily from his/her daily work experiences. Psychiatrists, for example, must assume critical risks in determining whether a patient is suicidal or homicidal. Overly conservative judgment can produce excessive restrictions on the patient, exposing the clinician to a lawsuit alleging violation of the judicial principle of treating patients in the least restrictive manner necessary. On the other hand, laxity can result in serious injuries to the patient and/or others, again subjecting the clinician to a possible lawsuit charging negligence. In return for shouldering these responsibilities of judgment, psychiatrists feel entitled to considerable autonomy. The fact that often there is no single accepted way to resolve a clinical problem reinforces the claim of autonomy. Competing claims about the relative efficacy of psychotherapy and drugs in treating acute schizophrenics, for example, require that psychiatrists practice on the basis of scientific evidence that is less than adequate.

Unclear treatment choices leave professionals vulnerable; they therefore hesitate to use the abstract rules of standards in passing critical judgment on their peers. The greater the degree of risk and the more ambiguous the clinical intervention, the more tenaciously the professional clings to his/her autonomy and resists external standards. Most professionals remain unimpressed by the fact that externally imposed standards afford protection as well as encroachment on one's autonomy.

Observability and Privacy

A profession by definition lays claim to a complex, sophisticated body of knowledge that is transmitted to its practitioners only through an extended and intensive educational process. In fact, as Zusman (5) noted, an essential characteristic of a profession is its incomprehensibility to outside observers. Psychiatrists can maintain their mystique since most treatment occurs in the privacy of the practitioner's office. Although privacy is essential in guarding patients' rights, it also severely limits observation by nonprofessionals. It is within a framework of nonobservable, complex tasks that psychiatrists evaluate professional performance through peer review which emphasizes clinical criteria; nonclinical criteria such as cost effectiveness are usually excluded from the assessment process.

Peer review limits external scrutiny and maintains ingroup control over clinical practice, but it is fraught with limitations. Zitrin and Klein (12) noted that small peer groups of already busy volunteer psychiatrists lacking staff or funding cannot be expected to investigate and judge cases involving the reputations and professional careers of friends and colleagues. Between 1970 and 1974, an APA district branch ethics committee considered 44 complaints against members. In only two cases did the committee vote for a finding of unethical conduct; in many cases the committee felt the charges were more than justified but lacked sufficient proof to warrant a negative finding. Zitrin and Klein reported that some members of this ethics committee wondered whether the committee merely served as a buffer between the profession and the public, since it was without the resources, objectivity, and perhaps the will to do more.

In reaction to the limitations of the kind of peer review that utilizes veiled prototypes of clinical practice, there is a growing insistence that effective quality control utilize explicit and empirical standards comprehensible to both laymen and professionals. Furthermore, it is believed that these standards should protect the interests of consumers as well as practitioners. How, then, can psychiatric care be meaningfully assessed without violating patient confidentiality?

No easy answers are yet available, but the medical record is a window for observing the quality of patient care. Rather than being the private working tool of clinicians alone, the medical record can also be used for arriving at evaluative and fiscal decisions. By studying the clinical record, a fellow practitioner or carefully trained evaluator can reconstruct the course of treatment and estimate its quality.

A promising feature in this development is the pressure placed on clinicians to specify the patient's problems and the treatments appropriate to them. Problem-oriented records are widely used in medical-surgical care, but their application to psychiatric services is relatively recent (13, 14). A related technique for sharpening the clinician's statement of patient problems and treatment expectations is goal attainment scaling (15). Therapeutic progress is assessed in relation to each problem on a five-point scale, ranging from the best to the worst expected outcome.

Clinicians resist evaluation technologies for various reasons. These range from assertions that evaluation

produces impersonal, mechanistic care to contentions that psychiatric treatment is a subtle, unfolding process that cannot be circumscribed within delimited statements of problems and goals. The more long ranging and intensive the clinician's treatment orientation (e.g., psychoanalytic psychotherapy), the more uncomfortable he/she will be with evaluations requiring that goal statements be included in the medical record. The briefer and more targeted the clinician's interventions, (e.g., symptom reduction through psychoactive drugs or behavior therapy), the more comfortable he/she will be with assessments by means of records review.

Perspective of Time

As bureaucrats strive to evaluate clinical practice via standards, they must recognize that professionals expect delayed rather than immediate scrutiny. Friedson and Rhea (4) noted that the sharing of judgmental observations among colleagues is a slow and limited process. Since a critical mass of discontent is necessary before colleagues will complain to each other about a peer's errors, long periods of time elapse before widespread opinion emerges about a professional's work. Even then, complaints lodged with such professional control forums as ethics committees may require years for review and adjudication. Thus routine utilization reviews, particularly if they are performed prospectively, are likely to be resisted; retrospective audits, however, are more compatible with professional norms and thus are more easily implemented.

Appropriateness of the Penalty

Professionals judge the appropriateness of bureaucratically established penalties against the norm of peer-approved penalties. The sanction most commonly employed by physicians against colleagues is a "talking to"—an action whose frequency varies with status and social distance (4). Cajoling is practiced more often among middle-level peers and between seniors and juniors than among senior peers. Even when a clinician adopts the more serious sanction of excluding an errant colleague from patient referrals, this usually is done informally and individually, not by the profession as a whole. Only in extreme instances do professional groups undertake a collective action that will affect a member's basic livelihood, e.g., seeking revocation of a license or registration. Bureaucratic penalties that have fiscal implications, such as exclusion from eligibility for Medicare and Medicaid reimbursement, therefore encounter stiff professional resistance. Mild rebukes for low-quality care are much more consistent with prevailing patterns of collegial disapproval and are more readily tolerated by professionals.

IMPLICATIONS FOR STANDARD SETTING

Organizations with clear-cut structures and operating procedures enable professionals to be productive, to advance new interests, and to live securely. Paradoxically, an organization's social-order needs require that limitations and conformity be imposed upon personnel. Given this social reality, is it possible to minimize the potential conflict between organizational managers and professional staffs with regard to quality-of-care procedures?

Many assume that the amount of control available to a group or an organization is absolute and fixed; increasing the power of one sector would thus automatically decrease the power of other sectors. As administrators gain increased authority to participate in the review of the quality of care, professionals fear that their own autonomy will suffer. An alternative conception of power and control is that they are not absolute and finite. Tannenbaum (7) suggested that the total amount of control exercised by an organization varies—it can increase or decrease. Within this perspective, altered and strengthened quality-of-care standards need not inevitably lead to struggles between administrators and professionals. Depending upon the nature of the standards and their enforcement procedures, both groups may benefit or suffer.

If we assume that appropriate quality-of-care standards can benefit *both* administrators and professionals, how should standards of psychiatric practice be designed and enforced? By extrapolating from Friedson and Rhea's (4) analysis of self-regulation in a medical group practice and Bellin's (6) experience in establishing regulations for Medicare providers, it is possible to suggest the following:

1. Clinicians will more rapidly accept and function within quality-of-care standards when they have helped formulate them. Standards perceived as established by individuals or bodies not traditionally part of the professional's frame of reference are more likely to be resisted. Furthermore, if the standards generate controversy, ad hominem issues soon supersede intellectual discourse. Dorsey and Sullivan (16) have urged physicians to help design review methodologies so as to minimize such problems as unrealistic standards and record keeping as an end rather than a means.
2. As a routine article of faith, professionals deem their personal interests to be necessarily identical with those of their patients. To suggest otherwise attacks the premises upon which many of the clinician's practices are founded. Quality-of-care standards should therefore reinforce positive practices and emphasize the personal rewards to be gained from modifying less satisfactory practices.
3. Standards developed by or with professionals are more readily accepted by individuals trained, socialized, and functioning within the profession's normative system than by individuals not dependent upon colleagues for esteem and trust. Such bodies as PSROs can enforce standards among psychiatrists subscribing to peer group pressures. The leverage and sanctions of governmentally administered bureaucracies are necessary primarily to maintain standards among those un-

concerned with, or alienated from, a professional normative system.

CONCLUSIONS

Clinicians functioning within well-established norms feel their prerogatives being eroded by inappropriate demands for data; administrators consider traditional peer review procedures inadequate for assessing the quality of patient care. If current tensions escalate, the paradoxical result may be that clinicians will produce masses of data for reviewers while simultaneously reducing their commitment to patient care. The clinician's annoyance with bureaucrats because of the necessity to complete endless forms may be converted into passive-aggressive behavior toward patients. Those responsible for accommodating the competing needs of clinicians and administrators can forestall this ironic eventuality by recognizing that both clinical practice and evaluation constitute means rather than ends. They must foresake their current preoccupation with assessing process and view the evaluation of outcome as the framework of mutual concern.

Mental Health Services in the Public and Private Sectors

BY LORRIN M. KORAN, M.D.

Analysis of data on mental health service providers indicates that in 1971 the private sector accounted for 34% of inpatient days, 86% of outpatient visits, 44% of expenditures by source of funds, and 51% of expenditures by receipt of funds. The author believes that mental health professionals must familiarize themselves with the economic interests influencing national health insurance proposals and with public policy making processes if they are to help preserve appropriate roles for the public and private sectors in mental health service delivery.

THIS ARTICLE is an attempt to provide more complete estimates of the volume of mental health services in the public and private sectors than have previously been available. Sharfstein and associates (1) have given the most extensive estimates to date. They limited their attention, however, to the public and private practice of psychiatry and did not consider mental health services rendered by other medical or mental health professionals in various settings. Moreover, as I will illustrate below, their estimate of outpatient visits to private psychiatrists was far too low. With national health insurance under debate and the extent of coverage of services for mentally disordered patients still unclear, a more complete estimate of the role of the private sector may benefit public policymakers and the public interest.

In 1975, Sharfstein and associates concluded that "there are no clear data available to permit adequate assessment of or definitive conclusions about the current relative roles of [psychiatry in] the public and private sectors, however defined, in the provision of mental health services" (1, p. 47).

The authors encountered several problems in their research. The exact numbers of psychiatrists in private practice and of persons under their care were not known. Moreover, some private practice psychiatrists also engage in part-time salaried practice in a public facility. In both the public and private sectors, the data on annual admissions and patient care episodes in mental health facilities were contaminated by duplications, i.e., patients treated in more than one setting in a year or treated more than once a year in the same setting. Finally, because public facilities receive private dollars (e.g., patient fees) and private facilities receive public dollars (e.g., Medicare), the boundary between the public and private sectors is blurred.

The analysis that I will present circumvents these problems in several ways. First, better estimates of the number of outpatient visits to private psychiatrists are now available. Second, the measures used to describe the volume of care—inpatient days, outpatient visits, and expenditures—do not depend on unduplicated counts of patients. Third, the boundary between the public and private sectors has been clarified by examining expenditures for mental health services by both recipients of funds and source of funds.

In order to build on the data assembled by Sharfstein and associates, I have examined mental health services delivered in 1971, the year they studied. A few of their estimates have been changed because better data are available. In addition, I have included data on services rendered by practitioners and facilities they did not study. No data are available, however, regarding some kinds of facilities, e.g., general medical clinics. Units of care have been apportioned according to the public or private ownership of the particular type of facility. For example, Sharfstein and associates assumed all federally funded community mental health centers (CMHCs) were in the public sector; in fact, only 45% were publicly owned (2). (However, 80% of CMHC funds were derived from government sources [3].)

THE MEASURES

Inpatient Days

Sharfstein and associates' estimate of inpatient days in residential treatment centers for emotionally disturbed children has been distributed according to the proportions of publicly and privately owned beds (4) (see table 1). Because CMHCs and residential treatment centers for disturbed children account for very small proportions of inpatient days, the redistributions do not result in substantial differences in the overall analysis. Estimates have been added for the number of inpatient days spent by mentally disordered persons in halfway houses, nursing homes, and personal care

Dr. Koran is Associate Professor of Psychiatry, Department of Psychiatry and Behavioral Science, State University of New York at Stony Brook, Stony Brook, N.Y. 11794.

The author would like to acknowledge the help of the National Institute of Mental Health Division of Biometry in providing NIMH publications and the technical assistance of Ms. Fran Melvin and Ms. Meta Rolston. He would also like to thank Mr. Carl Taube, Dr. Steven Sharfstein, and Dr. Irving Goldberg for their critical comments on the draft of this paper.

TABLE 1
Volume of Mental Health Care in the Public and Private Sectors in 1971*

Sector	Inpatient Days		Outpatient Visits	
	Number (thousands)	Percent	Number (thousands)	Percent
Public				
General hospital psychiatry units	2,178	0.8	1,219	1.8
Federally funded CMHCs	1,001	0.4	1,519	2.2
Halfway houses	160	0.1	—	—
Residential treatment centers for emotionally disturbed children	153**	0.1	—	—
Nursing and personal care homes	8,835	3.1	—	—
Freestanding outpatient clinics	—	—	3,206	4.6
State and county mental hospitals	95,584	33.9	2,171	3.1
Veterans Administration psychiatric hospitals	11,945	4.2	1,182	1.7
Public institutions for the mentally retarded	66,065	23.4	—	—
Federally employed internists and general practitioners	—	—	429***	0.6
Total	185,921	66.0	9,726	14.0
Private				
General hospital psychiatric units	4,794	1.7	1,661	2.4
Federally funded CMHCs	1,224	0.4	1,857	2.7
Halfway houses	1,768	0.6	—	—
Residential treatment centers for emotionally disturbed children	6,225	2.2	—	—
Nursing and personal care homes	77,781	27.6	—	—
Freestanding outpatient clinics	—	—	4,043	5.9
Private mental hospitals	4,293	1.5	506	0.7
Private practice psychiatrists	—	—	18,320	26.5
Private practice psychologists	—	—	2,757	4.0
Private practice internists and general practitioners	—	—	30,234	43.8
Total	96,085	34.0	59,378	86.0
Total	282,006	100.0	69,104	100.0

* Data are from Sharfstein and associates (1) unless indicated otherwise in table or text.
** 2.4% of government-owned beds multiplied by inpatient days from Sharfstein and associates.
*** 1.42% of outpatient visits to private practice internists and general practitioners (10).

homes and by mentally retarded individuals in public institutions for the mentally retarded.

In 1971, halfway houses serving the mentally disordered had 6,170 beds, with an occupancy rate of 85.6%. Only 8.3% of the beds were in government-owned halfway houses (5).

There were 1,073,000 residents in nursing and personal care homes in 1971 (6). The average daily census is assumed to have been 5% less than this. According to preliminary tabulations from the National Center for Health Statistics (NCHS) 1973–1974 nursing home survey, 9.64% of residents had a primary diagnosis of mental disorder and 13.64% had a primary diagnosis of senility (7). Thus 23.28% of all inpatient days and expenditures in these homes have been attributed to mental disorders. This is a conservative estimate (7); if one includes both primary and other diagnoses, 18.65% of residents were impaired by mental disorders other than senility and 58.34% were senile. Only 10.2% of beds in nursing and personal care homes were in government-owned homes (8).

In 1971, public institutions for the mentally retarded had an average daily census of 181,000 persons, or 65,065,000 inpatient days per year (6).

Outpatient Visits

Sharfstein and associates rejected as too high an APA task force estimate (9) of outpatient visits to private practice psychiatrists (8,000 private psychiatrists each with 55 patient visits per week for 48 weeks yielded 21.12 million visits, of which Sharfstein and associates estimated 6.21 million were in private mental facilities, resulting in an estimate of 14.91 million outpatient visits). They chose instead to increase by 50% an NCHS estimate based on a household survey. The increase was to correct for "hesitancy about reporting psychiatric care in a household interview" and yielded an estimate of 6.56 million outpatient visits. Despite the 50% increase, this estimate is almost certainly too small by a factor of 2.5 or more. For example, a national survey of physicians conducted in the fall of 1970 by the American Medical Association indicated that 10,907 psychiatrists (not including 1,182 child psychiatrists) whose major professional activity was "office-based practice" conducted an average of 34.1 office visits per week and worked an average of 47.9 weeks, yielding 17.8 million office visits per year (10). Approximately 1.4% of these visits may have been to federally employed physicians, since 1.4% of all "office-based" physicians were in federal employ. If these visits are subtracted, the estimate of office visits is 17.55 million. If we consider all psychiatrists with patient care activities (N =20,570), the estimate of office visits would have to be raised, and Sharfstein and associates' esti-

mate would be too small by a factor of much more than 2.5.

Fortunately, data are now available from a one-year (May 1973–April 1974) NCHS survey of 1,700 office-based, patient care physicians, including psychiatrists (11). This survey estimated 20.3 million office visits to office-based psychiatrists, which has been discounted 5% per year back to May 1971 to correct for increases in the number of psychiatrists. This discounting yields 18.32 million visits, which accords very well with the AMA survey estimate noted above.

The estimate of the number of office visits to clinical psychologists in private practice is based on an American Psychological Association survey, which indicated that there were 1,688 psychologists in full-time private practice in 1971 (7). Psychologists in part-time private practice (N=3,579) are not included in this analysis. Assuming that the 1,688 psychologists had the same average number of office visits per week (34.1) and worked the same number of weeks (47.9) as the office-based psychiatrists in the AMA survey noted above, the number of office visits is 2.757 million.

It is a bit more difficult to estimate the proportion of office visits to nonpsychiatric physicians that represent care for mental disorders, since the estimate depends largely on how the term "mental disorders" is defined. Estimates in the literature range from 5% to 47.6% (12–14). Ten percent has been taken as a conservative estimate of the proportion of office visits to internists and general practitioners that represent care for mental disorders. Patients with medical or surgical problems and unrelated or secondary psychiatric disorders are not included in this estimate. I have used the estimates of the number of office visits to internists and general practitioners in the 1973–1974 NCHS survey of office-based physicians. Unfortunately, the survey report did not break out visits to internists and general practitioners by diagnosis. Mental disorders, however (diagnosed according to the eighth revision of the *International Classification of Diseases, Adapted for Use in the United States*), accounted for 4.5% of office visits to all physicians, including surgical specialists. However, surgical specialists would be expected to care for fewer patients with mental disorders than internists and general practitioners, and this may partially account for the lower NCHS figure. Office visits to internists and general practitioners have been discounted 5% per year back to 1971 to account for increases in the number of physicians and physician visits.

Expenditures

Except where noted, data on expenditures in 1971 by source and by recipient of funds have been derived from table 1 in *The Cost of Mental Illness—1971* (7) (see tables 2 and 3). It was necessary, however, as indicated in table 3, to separate some of the figures in this study into public and private expenditures with the help of data on patient days, facility or bed ownership, or patient diagnoses from NIMH and other sources. Only expenditures for direct care services and drugs have been included.

TABLE 2
Expenditures for Mental Health Care in 1971, by Source of Funds

Source	Total Expenditure* (thousands)	Percent of Total
Federal government		
Medicare and disability insurance	231,960	2.6
Medicaid	550,001	6.2
Other	964,687	11.0
Total	1,746,648	19.8
State and local government		
Medicaid	542,202	6.1
Other	2,618,333	29.7
Total	3,160,535	35.8
Private sources		
Fees	2,652,217	30.0
Insurance	1,058,380	12.0
Other	216,850	2.4
Total	3,927,447	44.4
Total	8,834,630	100.0

* Dollar figures are derived from *The Cost of Mental Illness—1971* (7, table 1).

DISCUSSION

The addition of mental health service providers and facilities that Sharfstein and associates did not include leads to conclusions about the relative roles of the public and private sectors that differ considerably from theirs. As table 1 indicates, 34% of inpatient days occurred in the private sector, rather than the 12% estimated by those authors. Another striking difference is the estimated proportion of outpatient visits that occurred in the private sector: 86% versus 53%. Clearly, a more complete enumeration of mental health service providers and facilities suggests a much larger role for the private sector.

As table 1 indicates, the vast majority of inpatient days in the private sector takes place in nursing and personal care homes. Almost 60% of the cost of this care is paid for by private dollars (7). Federally funded CMHCs may currently account for a somewhat greater proportion of inpatient days in both the private and public sectors, since 536 CMHCs were operational by mid-1975, compared with 295 in 1971. In the public sector, the vast majority of inpatient days takes place in state and county mental hospitals and public institutions for the mentally retarded. Almost 90% of the cost of care in state and county mental hospitals is paid for by public dollars (7).

The large number of inpatient days accounted for by nursing and personal care homes reflects in part a shift in the locus of care for mentally disordered elderly patients from state and county mental hospitals to these facilities. For example, between 1963 and 1969 the percentage of mentally disordered patients aged 65

TABLE 3
Expenditures for Mental Health Care in 1971, by Recipients of Funds

Recipient	Total Expenditure* (thousands)	Public Sector		Private Sector	
		Amount (thousands)	Percent	Amount (thousands)	Percent
State and county mental hospitals	2,695,964	2,695,964	100.0	—	—
Other public mental hospitals (includes St. Elizabeths, federal prison psychiatric hospitals, and Veterans Administration psychiatric hospitals)	412,646	412,646	100.0	—	—
Private mental hospitals	281,348	—	—	281,348	100.0
General hospitals (includes 10% of Veterans Administration inpatient expenditures)	927,746	305,228	32.9**	622,518	67.1
CMHCs	284,955	128,230	45.0	156,725	55.0
Freestanding outpatient clinics (includes campus and military clinics)	481,219	295,477	61.4	185,742	38.6
Nursing and personal care homes	1,443,553***	147,242	10.2	1,296,311	89.8
Halfway and rehabilitation facilities	194,916	186,196	95.5†	8,720	4.5
Special programs for children (includes school programs and residential treatment centers)	303,915	123,282	41.0	180,633	59.0
Private practice psychiatrists	833,117	—	—	833,117	100.0
Private practice psychologists	79,336	—	—	79,336	100.0
General medical practice (includes private and federal internists and general practitioners)	358,325	27,065	7.6	331,260	92.4
Psychotherapeutic drugs	537,590	—	—	537,590	100.0
Total	8,834,630	4,321,330	49.0	4,513,300	51.0

*Totals and subtotals are derived from *The Cost of Mental Illness—1971* (7, table 1).
**Based on annual patient days in non-Veterans Administration government general hospitals plus 10% of annual patient days in Veterans Administration hospitals (4).
*** 23.28% of all costs for nursing homes (7).
†This is an overestimate, since some rehabilitation funds are used to pay private practitioners and private facilities.

or more in long-term institutions who resided in nursing and personal care homes rose from 52.7% to 74.8% (15). Many of these people may not be receiving active treatment for their mental disorders, especially in personal care homes that do not have nursing services. It may be that those who are not receiving active treatment would not benefit from it and that these homes therefore represent a more economical and humane way of providing custodial care than state mental hospitals. It may be, but this remains to be demonstrated (16).

Outpatient visits in the public sector, as shown in table 1, are rather evenly distributed across several facilities. In the private sector, internists and general practitioners account for more visits than do psychiatrists. Even if the estimated proportion of visits to internists and general practitioners for treatment of mental disorders is decreased from 10% to 4.5% (the NCHS survey figure for all physicians), these physicians would account for almost as many outpatient visits (15.075 million) as do psychiatrists (18.320 million). It should not be assumed, however, that the units of mental health care given by nonpsychiatric physicians are the same as or as effective as units of mental health care given by psychiatrists. About 77% of the cost of mental health care rendered by general practitioners and internists is paid for by private dollars (7). For psychiatrists in private practice, this estimate is 98%, which is undoubtedly an over-estimate, since no allowance was made for Medicaid payments to private psychiatrists (7).

Some recent national health insurance proposals have severely limited outpatient psychiatric services provided by psychiatrists but not those provided by nonpsychiatric physicians (17). This limitation probably reflected concern about the cost of long-term psychoanalysis (especially for individuals who are functioning well socially), a treatment nonpsychiatric physicians do not administer. Hiatt has discussed the need to limit access to expensive medical/surgical treatments in order to preserve finite resources for other treatments (18). The same argument may apply to long-term psychoanalysis, but a blanket limitation on all forms of outpatient care given by psychiatrists is neither medically justifiable nor economically necessary (19).

Of the estimated $8.8 billion expended on mental health services in 1971, about 20% came from federal sources, about 36% from state and local government sources, and about 44% from private sources (see table 2). Private sources pay for a larger percentage of all medical/surgical services than of mental health services; in fiscal year 1971, private sources accounted for about 64% of expenditures for all medical/surgical services (20). Although the exact percentages vary with the particular costs included and excluded, the greater participation of public dollars in paying for mental health services may stem partly from the large

public expenditures in state and county mental hospitals. Since the enactment of Medicare and Medicaid, however, federal and state percentages of expenditures for medical/surgical services have been increasing (20).

As is shown in table 3, expenditures for mental health services are received almost equally by the public and private sectors. More than half of the dollars expended in the public sector are received by state and county mental hospitals. In the private sector the largest recipients are nursing and personal care homes, followed by private psychiatrists and general hospitals. Private psychiatrists account for more dollars but fewer visits than internists and general practitioners, primarily because the psychiatric fee was assumed to be $35 per visit, whereas the fees for general practitioner and internist visits were assumed to be the follow-up office visit fees in these specialties (about $6.30 and $9.30 respectively) (7, 10).

In summary, with regard to mental health services in 1971, the private sector accounted for 34% of inpatient days, 86% of outpatient visits, 44% of expenditures by source of funds, and 51% of expenditures by receipt of funds.

CONCLUSIONS

As Sharfstein and associates noted, the volume of services (however measured) delivered by the public and private sectors is not the most important issue. They believe "a balanced mix of the two is essential" (1, p. 47). The most serious issues are making mental health (and general health) care accessible to all citizens, controlling costs without unwisely circumscribing services, and improving insurance coverage for mental disorders. Answers to these questions have been explored recently (17, 19, 21). A few additional points should be made, however.

Hall has questioned the effectiveness of mental health services: "Another problem for insurers is the failure of mental health professionals to document the effectiveness of various kinds of treatment. . . . For most physical conditions, this problem has largely been overcome . . ." (17, p. 1,083). Hall seems unaware that the effectiveness of medical and surgical treatments is constantly being tested and debated in the medical literature (22). These tests and debates create medical progress. Yet treatments with as yet uncertain benefits, such as coronary artery bypass surgery (23), certain drug treatments of cancer (24), and care in coronary care units (18) are not denied insurance coverage. If insurance coverage for medical and surgical treatments were limited to treatments for which incontrovertible evidence of effectiveness existed, a great many treatments would not be covered. In any case, the effectiveness of many pharmacological treatments in psychiatry is not in question (25–28), and evidence for the effectiveness of psychotherapy is accumulating (29–31). Insurers and public policy makers, however, must be helped to understand that "effectiveness" does not mean "cure." Even today, physicians can hope only "to cure sometimes, to relieve often, to comfort always."

Hall also stated that "mental health professionals in general have failed to provide the degree of cooperation and unanimity that many other health professionals have developed with reference to diagnosis (17, p. 1,087). That physicians other than psychiatrists often disagree regarding diagnostic criteria and findings, or diagnoses in particular patients, is not widely known or acknowledged (32, 33).

Muller and Schoenberg (21) have analyzed the economic interests shaping the future provision of mental health services by the public and private sectors. Mental health professionals must familiarize themselves with these economic interests and with the principles of influencing public policy making processes (34) to prevent insurance benefit packages, both private and federal, from determining patterns and modes of mental health care that conform poorly to past actuarial experience (19) and to their professional judgments about the best ways to care for their patients.

Utilization of Prepaid Services by Patients with Psychiatric Diagnoses

BY DONALD T. FULLERTON, M.D., FRANCIS N. LOHRENZ, M.D., AND GREGORY R. NYCA

The authors document and discuss the utilization of psychiatric services in a rural group practice before and after the institution of a prepaid health plan. They found that the utilization of psychiatric services increased dramatically during the first year of the plan's operation. The increase in outpatient utilization continued throughout the 3 years studied, but inpatient utilization decreased after the first year and later reached a level lower than that seen before the plan was instituted. One possible reason for the decline in inpatient utilization is that increased outpatient care prevents hospitalization.

THE INCREASED COVERAGE for psychiatric illness now provided by a variety of health insurance plans has caused considerable debate over the utilization of these services. Only incomplete data are available, and much of these are from experience in the pioneering prepaid groups of the 1960s. Goldensohn and associates (1) reported on a demonstration project conducted by the Health Insurance Plan of Greater New York from 1965 through 1968. They found that when mental health services were introduced into an existing prepaid medical practice the average annual consultation rate was 11 per 1,000 enrollees. They also reported a treatment rate of 7.5 per 1,000 enrollees. That is, 11 per 1,000 had a one-time consultation and 7.5 per 1,000 applied for treatment. This study reported inpatient experience for an 11-month period only. Dur-

Dr. Lohrenz is with the Department of Medicine, Marshfield Clinic, and Mr. Nyca is Director of Information Systems, Marshfield Medical Foundation, Marshfield, Wis.

This work was supported in part by grant 32 from the Wisconsin Regional Medical Program.

ing this period there were 19 hospitalizations and an average hospital stay of 18 days.

Glasser and Duggan (2) reported on the utilization of psychiatric services by the United Auto Workers union (UAW) under a prepaid plan in Michigan. During the first year of coverage for psychiatric illness the utilization rate was 6.6 persons per 1,000 eligible for outpatient service. The average number of visits was 8.5. In 1965 the UAW contract provided for inpatient coverage of up to 30 days. In 1967 the benefit was extended to 45 days. During 1965 4.1 per 1,000 eligible people were admitted to the hospital for psychiatric reasons. The median number of hospital days was 12.3. When the benefits were extended to 45 days the rate was 4.2 per 1,000 and the median length of hospital stay 12.6.

This report will document and discuss the utilization of psychiatric services at the Marshfield Clinic and St. Joseph's Hospital in Wisconsin for a 4-year period. Because of the unique service area it was possible to study the enrollees for 1 year before the comprehensive prepayment plan was begun. These same enrollees were followed for 3 years during their enrollment in the plan.

In a previous paper by Broida and associates (3) the impact of membership in the same prepaid plan was reported for all medical services. The present report is an expansion of one of the segments of that study.

METHOD

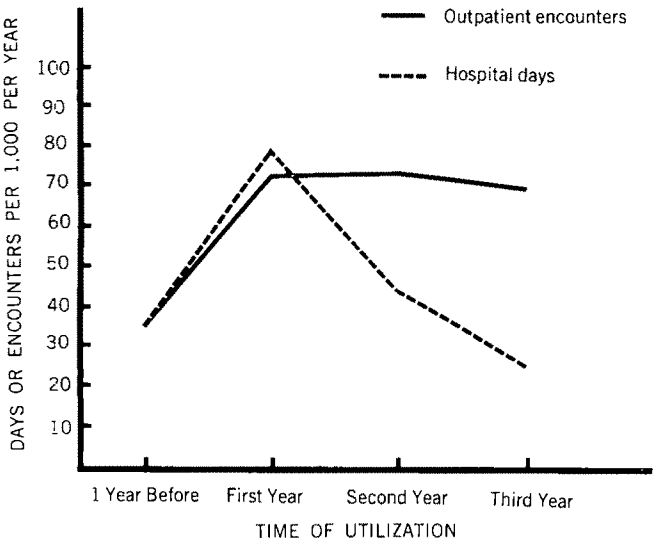
The Marshfield Clinic is a 128-physician multispecialty group practice, and St. Joseph's Hospital is a 450-bed general acute hospital with a 38-bed psychiatric unit. Marshfield provides the only psychiatric services for the area covered by the health plan. Psychiatric services are also available at the Marshfield Clinic on a fee-for-service basis and through a county-funded mental health clinic. These services are provided in both instances by the same staff, all of whom are employees of the Marshfield Clinic. This staff also provides all of the psychiatric services at St. Joseph's Hospital.

The Marshfield Clinic, St. Joseph's Hospital, and Wisconsin Blue Cross and Surgical Care Blue Shield of Milwaukee instituted a comprehensive prepaid health plan in March 1971 (the Greater Marshfield Community Health Plan). The plan provided two annual open enrollment periods of 30 days' duration. At this time anyone could join the program regardless of his health history. The provisions of the program included 10 outpatient visits (renewable after 90 days) to a psychiatrist, psychologist, or psychiatric social worker and 364 days of inpatient psychiatric care. However, the rules on the psychiatric ward at St. Joseph's Hospital limit the hospital stay to 90 days.

The study population consisted of everyone who joined the plan during the first 6 months of operation (N=8,377). The utilization of services by patients with psychiatric diagnoses was evaluated monthly during the preplan year and for 3 years after the plan was instituted. The utilization was reported in terms of services provided by the psychiatric department of the Marshfield Clinic as well as other clinical departments. The number of ambulatory encounters was recorded as well as the number of hospital days. Because the plan limited ambulatory services to 10 visits until July 1, 1974, utilization of psychiatric services on a fee-for-service basis and services throughout the mental health clinic were also reported.

The cases studied had a primary diagnosis of psychosis associated with organic brain syndromes, alcoholic conditions, drug abuse, nonpsychotic organic brain syndromes, functional psychoses, neuroses, personality disorders, psychophysiological disorders, situational disturbances, and behavior disorders of childhood, according to the *Hospital Adaptation of ICDA (H-ICDA)* (4) categories 296.0–316.9. Excluded were stammering, stuttering, and other speech disorders (316.0); specific learning disturbances (316.1); tics (316.2); cephalalgia (headaches) (316.8); and other special symptoms (316.9).

RESULTS



Approximately 3,000–3,500 of the study population were employees of St. Joseph's Hospital or the Marshfield Clinic and their families. The remainder of the enrollees came from other groups or joined during the open enrollment period. It was possible to obtain retrospective data on 7,799 person years for the year before enrollment in the plan. (A person year in our tabulations is a composite based on person months; a person month is 1 person eligible for benefits for 1 month.)

In the first year on prepayment 8,097 person years were reported. In the second year on prepayment it was possible to study 7,314 person years, and in the third year, 6,486 person years. The index year began in March 1971. The figures in the nonindex years are lower than those for the index year because some people did not live in the area for an entire year before the institution of the health plan and consequently could be studied for only part of a year. During the second and third year of operation of the plan a small number of enrollees dropped out of the plan or moved out of the area and consequently were studied for only the portion of the year that they were members of the plan.

The ambulatory encounter rate with the psychiatric department for the year before enrollment in the plan was 36.7 per 1,000 per year (286 encounters). During the first year on the plan the utilization rate rose to 71.9 (582 encounters). The second year it was 73.1 (535 encounters), and the third year it was 67.2 (436 encounters) (see figure 1).

The ambulatory encounter rate for psychiatric disorders with nonpsychiatrists in the Marshfield Clinic was 18.6 per 1,000 per year (145 encounters) the year before enrollment in the plan, 33.2 (269 encounters)

FIGURE 1
Utilization of Psychiatric Department's Services by Patients with Psychiatric Disorders Before and Under Prepayment Plan

the first year on the plan, 26.8 (196 encounters) the second year, and 35.8 (232 encounters) the third year on the plan.

Both psychiatrist and nonpsychiatrist providers had an ambulatory encounter rate of 55.3 per 1,000 per year (431 encounters) the year before enrollment. The first year on the plan there were 105.1 encounters per 1,000 per year (851 encounters) with all providers, the second year, 99.9 (731 encounters), and the third year, 103.0 (668 encounters).

The hospital utilization rate for the psychiatric department was 36.4 hospital days per 1,000 per year (284 hospital days) the year before enrollment in the health plan. This figure rose to 78.9 (639 days) the first year on the plan. The utilization rate fell to 45.5 (333 days) the second year and 24.7 (160 days) the third year (see figure 1).

The hospitalization rate for psychiatric diagnoses treated by nonpsychiatrists was 2.8 hospital days per 1,000 per year (22 days) the year before enrollment, 0.5 (4 days) the first year of enrollment, 4.4 (32 days) the second year, and 5.9 (38 days) the third year.

The hospital utilization rate for both psychiatrist and nonpsychiatrist providers was 39.2 hospital days per 1,000 per year (306 days) the year before enrollment, 79.4 (643 days) the first year, 49.9 (365 days) the second year, and 30.5 (198 days) the third year of enrollment in the plan.

The utilization data include visits made to the psychiatric department of the Marshfield Clinic after the plan limitations for ambulatory visits had been exceeded. These visits were paid for by the individual or by the Wood County Mental Health Service. During the first year of experience with the plan the study group made 215 visits outside the plan, the second year they made 107 visits outside the plan, and the third year they made 42 visits outside the plan.

COMMENTS

This study shows a dramatic increase in the utilization of services for treatment of psychiatric disorders after the institution of a prepaid program. Both outpatient and inpatient utilization doubled the first year of plan operation. The increased rate of outpatient utilization of services for psychiatric disorders continued throughout the 3 years studied. Inpatient utilization, however, fell after the first year and reached a level lower than the preplan level.

It is also of interest that during the first year of the plan's operation almost half of the visits made to the psychiatric department of the Marshfield Clinic were made outside the provisions of the prepaid plan. During the third year less than 10% of the outpatient visits to the psychiatric department were made outside the provisions of the plan. It is our belief that many of the enrollees in the plan were not aware of the limited psychiatric provisions of the plan during their first year because most visits outside the plan did not represent people who had exceeded 10 visits, the maximum number allowable. It is our impression that the 42 visits made to the psychiatric department during the third year of the plan represented visits made by patients who had exceeded the limit, which had been raised to 15.

This study demonstrates the impact of the institution of a comprehensive prepaid plan on both ambulatory and hospital utilization. There is a broad area for speculation on the reasons for these changes. The following hypotheses are offered as speculations on the reasons for the reported changes in the utilization of services. It is hoped that these speculations might be useful in examining the experiences of other groups.

The observation that the rate of hospitalization increased dramatically during the first year of the plan and then fell to below preplan levels may represent the effect of case finding. After prepaid services become available to a population there is an increase in first visits to psychiatrists; therefore, a number of problems that require hospitalization but that were not treated previously for economic reasons are uncovered. After this population has, in effect, been screened and people with preexisting psychiatric diagnoses have been hospitalized, the rate of hospitalization falls because a group of patients with serious problems has been treated.

We observed that the declining rate of psychiatric hospitalization in the second and third year of the plan coincided with a continued high utilization of outpatient services. It is quite possible that the declining rate of hospitalization was due to the fact that increased outpatient treatment prevented hospitalization. Of course, this is a popular idea in psychiatry; indeed, it was the feeling of the psychiatric department at the Marshfield Clinic that by making outpatient treatment more available we were preventing hospitalizations because patients were utilizing outpatient resources more.

The increase in the utilization of both inpatient and outpatient psychiatric treatment matches the experience of the Marshfield prepaid plan with other diagnoses. It has been the experience of the Marshfield plan that the utilization of both inpatient and outpatient medical services increases dramatically after the institution of the plan.

It should be noted that the Marshfield Community Health Plan is different from the prepaid plans reported previously (1, 2). One difference is that, unlike the Michigan United Auto Workers plan, which was limited to a group of workers in one industry, the Marshfield plan was open to anyone who wished to join, regardless of past health history. It is possible that this plan was self-selecting and that individuals who were aware of their poor health joined the plan with the intention of utilizing psychiatric services that they had postponed previously for economic reasons.

Our best guess is that the inpatient utilization rose during the first year of the plan and then fell because a number of cases of severe psychiatric illness were uncovered by the newly available psychiatric services and that after the plan had been in operation for some time outpatient psychiatric treatment was able to prevent hospitalizations.

Milieu Therapy: Toward a Definition for Reimbursement

BY LOUIS E. KOPOLOW, M.D., AND GENE D. COHEN, M.D.

The authors identify certain essential elements and processes within the milieu therapy approach that could provide the basis for reimbursement of this treatment modality under insurance. They also examine a philosophical framework, various guidelines, and a mechanism for accountability in the use of this form of treatment.

DESPITE MILIEU THERAPY'S long history as an important element in psychiatric treatment (1) in day and night hospital programs and 24-hour inpatient settings, the provision of this service has been recently used as the basis for denial of insurance benefits, e.g., by the Federal Employees Health Benefits Program. Such denials have already produced several suits and will undoubtedly produce more unless an accepted standardized definition for reimbursement can be reached.

Dr. Kopolow is Coordinator of Patients' Rights and Advocacy Programs, Division of Mental Health Service Programs, and Dr. Cohen is Chief, Center for Studies of the Mental Health of the Aging, National Institute of Mental Health, Alcohol, Drug Abuse, and Mental Health Administration, Parklawn Building, Rm. 11-105, 5600 Fishers Lane, Rockville, Md. 20852.

PROBLEMS OF DEFINITION

Although most psychiatric facilities claim to have a therapeutic milieu, few are able to show a truly coordinated program worthy of reimbursable status by third-party payers. Part of the problem has been the very popularity of the concept of milieu treatment. The studies of social scientists such as Mead (2), Srole and associates (3), Rogler (4), and Hollingshead and Redlich (5) have emphasized the importance of social variables in the development of mental illness. Another popularizing trend in the development of milieu therapy has come from the hospital-cultural-social studies of Goffman (6), Stanton and Schwartz (7), and Maxwell Jones (8), who described therapeutic and nontherapeutic aspects of staff-patient relationships. With such influential scientists emphasizing the importance of milieu, it is not surprising that many hospitals are attempting to replicate successful models of milieu therapy in their programs.

Problems have arisen, however, because programs developed for specific facilities, i.e., small, private, heavily staffed institutions, are unable to be successfully superimposed on large state hospitals due to structural variables such as size, administrative and legal

control, and financing. Another problem of popularization of the concept has been that some mental health professionals have viewed milieu therapy as a smorgasbord from which they could select portions of their choosing and ignore aspects with which they did not agree.

To help resolve some of these problems about milieu, it would be useful at this juncture to proceed from a dictionary definition to a working and reimbursable definition of milieu therapy. *Webster's Third New International Dictionary* (9) defines "milieu" as "environment" or "setting." Thus milieu, in and of itself, is not therapy or necessarily therapeutic; rather, it is merely a setting or framework. Depending on how it is structured or designed it can become therapeutic, as in a therapeutic community of the psychiatric ward or day hospital.

What, then, is milieu therapy? Unlike traditional dyadic psychoanalysis, which focuses on internal dynamics, milieu therapy addresses the external factors that affect behavior and, ultimately, the adaptive capacities for those involved. To be effective, a milieu must be sufficiently flexible to meet changing environments and the constant readjustment of individual behavior to internal and external pressures. As Almond pointed out, "No one setting can handle all problems, no problem can respond to all milieus, and not all milieus can survive in the same societal framework" (10). It is no more reasonable to expect the adequacy of a single paramount approach in addressing external dynamics than it is to expect it for internal dynamics (witness the multiplicities and approaches in psychotherapy). Therefore, depending on the person and the problem, the dyadic as well as the milieu approach will vary.

A milieu therapy program provides and creates opportunities for corrective emotional experiences and graded experiences in learning coping techniques. Within a given milieu, individual components can be varied according to the individual problems or needs of the patient. These components, including group therapies and activities, occupational therapy, recreational therapy, supportive measures, and medical/psychiatric management, do not exist independently of each other, but rather interrelate to produce a product greater than the sum of its individual parts. Milieu therapy is the process by which the total setting in which the individual lives and functions, including the activities and interactions within it, is structured in accordance with treatment goals and changing internal and external dynamic factors, with the aim of achieving or supporting maximum improvements in the patient's condition. To the extent that the process is carried on, the milieu becomes actively therapeutic.

FUNCTIONS OF THE MILIEU THERAPY APPROACH

In the underlying program the therapeutic milieu has three important functions—rehabilitation, support, and medical/psychiatric management of the patient. Within the milieu these functions overlap. Rehabilitation seeks to return the individual to a level of functioning equal to or, ideally, better than that prior to the onset of his illness. Support is achieved through the stability, constancy, and reality testing that characterizes a therapeutic milieu, and it gives the patient the building blocks from which to restructure an ordered existence. A final function of the therapeutic milieu is in the area of medical/psychiatric management. The observation of a patient's behavior in various milieu programs, such as occupational therapy or group therapy, enables the mental health professional to make adjustments in the patient's treatment plan to facilitate consistent improvement (11). These adjustments might include an increase or decrease in psychiatric medications, addition of new programs, or abandonment of activities not found to be of value.

The therapeutic milieu focuses on the reduction of behavioral disturbance and the restructuring of ego functions. To the extent that treatment activities within a setting can be coordinated and beneficially structured to accomplish the previously cited programs and goals, one has a therapeutic milieu. Although milieu is important for every person, that is not to say that all psychiatric patients require milieu therapy. The indication for milieu therapy becomes obvious when one's external environment (i.e., home situation, family relationships, job, and peer group interaction) is in turmoil or the equilibrium between one's internal dynamics and one's perception of the external environment is disrupted. Thus the need for milieu therapy emerges with identifiable problems in one's milieu, and not necessarily with diagnosis.

Milieu therapy needs to be viewed along a continuum. Schematically, at one end of the continuum would be psychoanalysis, with its attention to internal dynamics and internal structural elements. At the other end of the continuum would be milieu therapy, with its focus on external dynamics, external structural elements, and internal perception of external environment. A candidate for psychoanalysis who had a sufficiently stable milieu would not require milieu therapy. However, a crisis or breakdown in this patient's milieu might lead to hospitalization, where the dyadic relationship would be continued but would be complemented by therapeutic milieu approaches. In this sense, milieu therapy might be necessary as either a primary or a complementary approach to treatment, not limited by narrow considerations of treatment of choice but rather seen as an essential part of the overall treatment program.

A BASIS FOR REIMBURSEMENT

Having addressed the more important theoretical considerations underlying milieu therapy, we will now examine the issue of the basis for the reimbursement of this treatment by third-party payers. In general,

milieu therapy contains two features not found in the absence of a milieu approach.

1. *A more comprehensive set of therapeutic interactions available to the patient*. It is true that many of these interactions (e.g., communications between patients and communications between a patient and a paraprofessional) take place whether or not a milieu approach is used, but unless they are actively reviewed in a structured clinical manner, they are much less likely to be therapeutic.

2. *A method of assuring that the various interactions experienced by a patient do not occur in isolation from one another*. This relates to the process of shaping a milieu and coordinating what occurs within it—a process, as alluded to previously, that is fundamental in facilitating the therapeutic effect of a milieu. Clearly, this is a true quality care orientation, but one that too often is not adopted because of the time (and therefore cost) involved.

The elaboration of these two features could provide a framework for a reimbursable definition of milieu therapy. It is apparent that in the milieu approach interactions are not only greater in number and scope, but also more interwoven. Furthermore, the process of coordinating these various interactions is crucial to the efficacy of the milieu approach. This process contains a diversity of potential activities, ranging from altering the overall treatment plan to examining the countertransference issues and conflicts that patients catalyze with the staff (e.g., the patient maneuver of playing off one staff member against another). This process, taking into account both the patient and his treatment community, aims at a better assessment of the patient's everyday life and perhaps a better sense of how he gets out of step with it.

It is also important to view the patient's interactions with attention to the physical setting in which they occur, for the setting itself can be facilitating or impeding. Considerations in this regard include attention to the ambience of the ward, distances between beds, the use and breakup of space, such as with social corners, the dayroom, whether doors are locked or open, and so forth. Again, this is an involved and time-consuming process, but it is this process that makes a milieu therapeutic and not just a setting.

Structure of the Milieu

As alluded to earlier, fundamental to what facilitates the therapeutic effect of a milieu is the process that shapes its structure or design. The elaboration of the treatment elements that comprise this process and should be common to all forms of milieu therapy can provide a generalizable basis for reimbursement. Such elements might include the following:

1. Identification of the problems that will be addressed by the milieu approach with each patient.

2. Development of an *individualized*, constantly adapted treatment plan that would include goals and delineate how the milieu is being used to alleviate the patient's presenting problems, as well as other problems subsequently identified.

3. Sufficiently frequent *team* meetings that a) delineate in the records the various interactions of the patient that are of therapeutic concern (e.g., patient-patient, patient-staff, family-staff, patient-treatment modality, and patient-physical environment interactions); b) delineate in the records the issues arising from each of these interactions and how they might be addressed; and c) focus on the coordination of the various interactions and staff input, with attention to their common and/or contrasting issues.

Perhaps the most difficult part of the milieu approach from the management perspective is the importance of coordinating staff input and the amount of time that this can require. In this respect, the experience of Artiss might be enlightening. In his book *Milieu Therapy in Schizophrenia* (12) he described a milieu approach that he adopted in treating schizophrenic soldiers on the ward of a military hospital. He emphasized that "operationally, I have found that I must spend 40 percent of my time with the staff." He then anticipated the next question—or expression of skepticism, if you will—and acknowledged that

> Such an elaborate system of conferences and discussions seems preposterous on the face of it, in a group whose sole responsibility is the treatment of a small handful of schizophrenic soldiers. It could be easily derogated as a "Parkinson's Law" sort of effect in which a small bureaucracy solidifies itself by finding new duties whose sole function is the continuation of the bureaucracy as such. Critics might also suggest that this 40 percent of the doctor's and staff's time might well be reduced to 10 percent and the remainder given to patients.
>
> Indeed, no one could be more empathetic with these critics than I. Superficially, it doesn't seem reasonable that a doctor should be required to spend so much time with a group of normals, just to help them keep functioning. However, each step in this direction has been necessary in order to keep the communication system sufficiently free from distortions that it could deal effectively with patients. (12, pp. 17, 18)

Two other points might also be made here. First, the community (i.e., the military) in which Artiss' ward operated was already highly structured, and still he had to invest 40% of his time in it. The second point, mentioned previously, is that what we really are concerned with is quality care. In this regard, is such an investment of time really preposterous? Certainly in Artiss' case it was not, since his ward was significantly therapeutic.

Accountability and Cost

To further strengthen the basis for reimbursing milieu therapy, accountability measures might also be considered. For example, during the process of hospital certification the surveyors should ascertain the following two points.

1. The facility has established predetermined points of concurrent review by a utilization review com-

mittee. This review need not include every patient but it could focus on a sample. Its value would be in demonstrating—if not assuring—the ongoing efficacy of the particular milieu approach.

2. The facility's milieu therapy program meets appropriate standards (such as the documentation of care noted previously). A facility's milieu therapy program should attain a reimbursable status if it has demonstrated that a working form of milieu therapy is in operation and that the necessary accountability measures have been implemented.

A final area for consideration in developing a reimbursable definition for milieu therapy is the determination of how charges for such treatment are to be made. One solution to this problem might be to include the milieu program under hospitals' or other facilities' (i.e., partial hospitals) daily "hotel and nursing charges." The cost of increased staff time involved in creating and maintaining a therapeutic milieu, such as the one described earlier in this paper, can easily be computed and added to existing daily charges. To handle problems such as reimbursement for nonstaff participation in milieu program planning (i.e., the patient's therapist), an agreed-upon consultation fee can be established. Whatever mechanism is finally established for the reimbursement of the cost of the therapeutic milieu, it is clear that this modality is essential to an effective treatment program and needs to be supported and promoted.

CONCLUSIONS

Milieu therapy is the treatment process by which the total setting (including the activities and interactions occurring within it) in which the individual lives and functions is structured in accordance with treatment goals and changing internal and external dynamic factors, with the aim of achieving or supporting maximum improvement in the patient's condition. The medical record should document the identification of problems requiring milieu treatment; the development of an individualized, constantly adapted treatment plan showing the methods to be used; and team meetings focusing on the patient's interactions with various components of his milieu. In order to achieve reimbursable status, the milieu therapy program must also show evidence of accountability, utilization review, and the meeting of appropriate standards.

Psychotherapy Fees and Residency Training

BY STEFAN A. PASTERNACK, M.D., AND PHILIP TREIGER, M.D.

Many residents in psychiatry tend to ignore their patients' attitudes and behavior concerning payment of fees for psychotherapy. The authors report on a new fee policy program designed to earn additional revenue for a low-fee outpatient psychotherapy clinic; they stress the therapeutic importance of resident and patient attention to fee-related issues.

FUNDING CUTBACKS for psychiatry training programs have made it necessary for academic departments of psychiatry to generate new revenues in order to maintain existing educational programs. We studied potential revenue from a resident-staffed outpatient psychotherapy clinic and found that large sums of money can be earned by residents working in the traditional low-fee psychotherapy clinic associated with most training programs. How do residents learn about fee-related issues and how do they handle them in psychotherapy with patients? Relatively few contemporary writers have discussed this subject in basic psychiatric works, although there are some notable exceptions (1–6).

THE PROBLEM

When this study began, residents were asked to submit data regarding the fees charged to and collected from each patient with whom they worked in individual, group, or family psychotherapy. The outpatient psychotherapy clinics of the Department of Psychiatry, Georgetown University Medical Center, had a low-fee schedule based on various income and insurance characteristics. Fees were to be assigned to patients during the intake and evaluation period, and the residents were to supervise the patients' payment of fees to the clinic. Since little income was being generated despite a large volume of outpatient hours, it was clear that the residents' fee-setting practices were questionable. They tended to rationalize their extraordinary departures from usual practice with a variety of lengthy explanations. Many residents simply ignored the entire matter, never bothering to determine whether their patients paid their fees. As a result, the patients often made no payment in spite of repeated billings and notices from a collection agency. It was common practice for residents leaving the program to transfer cases with large outstanding bills. Even patients being charged $1 or $2 per session often owed hundreds of dollars. The residents had colluded with patients and then denied the impact of this collusion on their work. They kept no financial records of any transactions and were therefore able to claim ignorance. Some discarded the bills they were supposed to give to their patients. The residents overlooked flagrant fee violations by patients and accepted very improbable explanations for failure to pay. The residents tended to ignore the possible impact irregularities in fee behavior might have on the conduct of psychotherapy.

It was clear that the residents had deep doubts about the relative value of their therapy work. They felt guilty about charging for their services. Some thought it was too much to ask of the patients to attend the residents' clinic and pay for it. Many admitted to feeling anxious while discussing fee issues. They needed help in order to clearly see the underlying transference and countertransference issues involved. Too often and too easily they fell into neurotic conspiracies with their patients; treatment suffered, the clinic was deprived of important revenue, and the training function was also undermined. Some residents acted out against the department by abetting nonpayment of fees, by not assigning proper fees, or by attempting to offer special arrangements.

THE SOLUTIONS

Once these problems were clearly delineated, a number of clinic policies were established to resolve the financial and training issues involved. Each resident was assigned a minimum of 40 psychotherapy hours per month. The clinic fee scale was publicized, and the residents were required to promptly submit monthly billing sheets on which they listed each patient, the dates of sessions, and the hourly fee. After a clinic billing sheet with each resident listed was prepared, it was possible to see at a glance if the residents were doing their minimum work and charging appropriate fees. When a resident's output (number of reported therapy hours) declined, he was asked for an explanation. This procedure helped to identify residents who had diffi-

Presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

culty keeping any patients in therapy and others who had specific problems with certain types of patients. Discussions about the residents' personal attitudes toward money (their financial goals, their own experience with money matters, and their expectations) were gradually expanded to include concern about cutbacks in funding and the threat to the integrity of the training program.

The residents eventually realized the importance of their work in providing revenue for the department. They became more aware of the potential value of their work and had an opportunity to explore fee issues that might have been overlooked until they began private practice. Discussions about third-party payers, the rising cost of mental health care, and the administrative organization of the clinic resulted in the hiring of an accountant to devise a simple bookkeeping system, adaptable to future private practice, for the residents to use. A double bookkeeping developed as a result of the requirement that each resident should know exactly what each patient was being billed and what he was paying. A secretary, who maintained a central set of books based upon figures taken from the monthly billing sheets, prepared each patient's bill and gave it to the resident. When the residents gave out their bills each month the transaction was personal, i.e., between doctor and patient rather than clinic and patient. The patients paid the residents directly with checks made out to the clinic. As a result of this procedure, the residents were always up to date on the patients' behavior and were able to immediately investigate late payments or other complications. Successive groups of residents rotating through the clinic became familiar with the new practices.

Of special importance was the heightened attention that all psychotherapy supervisors were asked to give to fee issues. It was important that such issues be thoroughly understood in the overall context of the patient's dynamic emotional conflicts. The residents were also required to submit to the clinic director quarterly reports on all cases, reviewing psychotherapy work and including comments about the fees being charged and collected. It was deemed just as important to avoid overzealous residents overcharging patients as it was to prevent inattentive residents ignoring fee issues. The new system ran smoothly for three years.

PATTERNS OF BEHAVIOR

A number of patterns of patient and resident behavior emerged as highly likely areas of fee "misconduct." One common patient pattern was the request for a lower fee, which was more often than not inappropriate than realistic and seemed to reflect a testing of the therapist's willingness to abet dependency. Some residents easily succumbed to the patient's wish to be treated with special indulgence and were likely to overlook the dependency issues implicit in such demands. Schizophrenic patients in particular seemed to be adversely affected when their therapists complied with requests for lower fees, and it was necessary for residents to be extremely alert to the complex fantasies that patients attached to any variation in the fee.

Dealing with insurance companies was a common problem. In general, patients tried to remove themselves from responsibility for their fees, leaving the doctor to negotiate with the insurance company. This tendency required careful clarification and often led to discovery of immaturity, reluctance to take responsibility in other areas of life, and unfulfilled dependency yearnings. Other patients tried to persuade the residents to misrepresent the initial date of treatment if they had obtained insurance coverage after that time. Some patients experienced conflict when their insurance companies sought information. One patient was indignant that the clinic would violate privacy and refused to explore the fact that he had made the claim to the insurance company and then did not want the doctor to give the required information. He secretly and then openly resented the need for a report, and therapy was almost sabotaged. It became clear that fee-related issues can easily interfere with the working alliance in therapy. Careful and frank discussions with patients in psychotherapy are necessary when dealing with issues of third-party payment. In some instances resistance to therapy may take the form of deviant fee behavior and all attention may be focused on the fee. However, such instances must be thoroughly explored for superficial and deeper meanings in order for therapy to progress. Failure to attend to fee-related issues on multiple levels may result in corruption of the therapy if not its complete destruction.

FINANCIAL OUTCOME OF THE PROGRAM

Over a three-year period the new fee policy resulted in a four-fold increase in clinic income. The residents took pride in their real contribution to the department and their training was substantially enhanced. Sensitivity to "money behavior" and fee training added a degree of sophistication to their interaction with patients. In the words of one resident, therapy work became more "real."

Numerous problems continued to arise—the most controversial was the question of charging for missed appointments. Clinic policy required the residents to explore with their supervisors any instance of missed appointments, late cancellations, and the appropriateness of charging in case of illness or family emergency. General guidelines encouraged holding the patient responsible for his appointments, but the residents were allowed to use their judgment. Some expected the patient to pay for every missed appointment regardless of the circumstances. Others struggled for what they considered to be fair solutions. The most critical point, however, was that this behavior would now be looked at closely.

It became easier for the residents to see how child-

hood patterns of behavior can be aroused during therapy and how at different phases of therapy a patient will miss many appointments, while at other times such resistances are not needed by the patient. The residents have been encouraged to set firm limits but also to be empathetic and understanding and to view the fee behavior as part and parcel of the overall therapy work. Focusing on fees helped bring to light the hidden meanings of missed appointments and made it necessary for the residents to explore them.

CONCLUSIONS

Training in psychotherapy involves knowledge about the setting and collecting of fees just as much as it does the establishment of other boundaries in therapy. Residents can and should be helped to deal more realistically with fee matters. In addition, attention to fees can enable residents to substantially increase revenues within the framework of a low-fee clinic. At a time when traditional sources of revenue are declining, it is important not to overlook any legitimate source of revenue.

Free Psychotherapy: An Inquiry Into Resistance

BY JAMES L. NASH, M.D., AND JESSE O. CAVENAR, M.D.

Psychotherapy for which the patient is not charged, such as that provided by the Veterans Administration system, can lead to unique conflicts and resistances within treatment. Patients may depreciate the value of therapy, feel obligated to the therapist, or expect him to make inappropriate nonfinancial demands. The authors present five cases illustrating that lack of a fee may become the focus of insoluble resistances to therapy, and suggest that, particularly in training situations, a token fee should be charged to obviate these difficulties.

FEE ARRANGEMENTS are a major aspect of the psychotherapy contract, and continued exploration of the patient's feelings about the fee typically leads to the uncovering of deeper conflicts. We wish to describe some of the resistances encountered in offering insight-oriented psychotherapy in a payment-free setting.

The Mental Hygiene Clinic of the Durham Veterans Administration Hospital is staffed in part by second-year residents learning intensive psychotherapy under the supervision of the authors, both of whom are psychoanalysts. Since the veteran may not be charged for his care, and in many cases is "paid" to obtain it, (e.g., by having travel expenses reimbursed) the fee never becomes a focus of the patient's treatment.

Dewald (1) discussed the importance of setting an appropriate fee. If it is too low, the patient may depreciate the therapy or, alternatively, may feel obligated to the therapist, inhibiting the expression of any anger arising in the transference. Likewise, a therapist who feels guilty for accepting money for his services or who has an excessive need to be liked, admired, and seen as giving may set the fee too low to avoid negative transference feelings but adopt unconscious expectations of a "return of the favor." The patient may also question the therapist's motives in setting a low fee, assuming special interest or harboring the fantasy

The authors are both Assistant Professors, Department of Psychiatry, Duke University Medical Center, Durham, N.C.; they are also with the Veterans Administration Hospital, 508 Fulton St., Durham, N.C. 27705, where Dr. Nash is Director of the Mental Hygiene Clinic and Dr. Cavenar is Chief of the Psychiatry Service.

Opinions expressed herein are those of the authors and do not necessarily reflect the views of the Veterans Administration.

that the therapist will make some nonfinancial demand of him. Finally, a low fee may be a source of difficulty with patients for whom manipulation of objects has been an important part of their psychopathology. These patients may feel triumphant and thus influence the treatment from the outset in a variety of ways.

According to Gedo (2), retained money may represent a transitional object for the patient, in that nonpayment of the fee may serve as an unconscious attempt to deny the patient's separateness from the therapist.

There is disagreement over the need for the patient to sacrifice for therapy. Menninger (3) warned that the treatment "will not go well if the patient is paying considerably less than he can reasonably afford to pay. It should be a definite sacrifice for him, for *him* and not for someone else . . . innumerable complications arise if the patient pays for analysis with the largess of a relative, a friend, or a Foundation to which he has no effective responsibility for repayment of some sort." Allen (4), however, felt that third-party payment presents no problem and that the patient does *not* have to suffer hardship for effective psychotherapy to occur. He held that the patient need only be *responsible* for the fee, regardless of who is paying for it; this arrangement may be unsatisfactory, however, if a family member pays the bill.

Enforced absence of the fee compounds the difficulties. If the beginning resident or his supervisor is not alert to particular resistances that may be manifested, the treatment may founder. In fact, as the following case material demonstrates, some of these resistances cannot be handled effectively at all.

CASE REPORTS

Case 1 illustrates a situation in which free treatment generated overwhelming guilt in a patient with an obsessional character structure and many reaction formations against dependency.

Case 1. The patient was a 30-year-old man whose father was a successful and hard-driving merchant. He had been a popular and athletic child. After graduation from a leading university, he worked as a junior executive and was then drafted. While serving in Viet Nam he had several episodes of paresthesias and transient blindness, and was ultimately diagnosed as having multiple sclerosis. After discharge he joined his father in business. He viewed his employment there as his father actually "taking care" of him and supporting him, since he was unable to work much of the time because of his illness. He felt guilty over receiving money from his father, calling it a "handout." He complained that since learning of his diagnosis he had been lethargic and depressed, with no motivation. He was aware of a relationship between his emotions and his multiple sclerosis symptoms; when he became angry with his demanding father his paresthesias worsened.

The patient had seen a private psychiatrist for 10 hours but felt he couldn't afford to continue. He was uncertain, however, about paying nothing. He clearly viewed the lack of a fee as another handout. He was referred to a second-year resident for twice-weekly psychotherapy. At the end of the third hour he asked to pay something for his treatment. The resident attempted to explore the meaning of this request, but the patient was only able to express a vague but pervasive discomfort with the nonpaying arrangement. When it was explained that payment was impossible within the VA system, the patient requested referral to the psychiatric service of a local university. Interpretations were made suggesting that he viewed the therapy as another handout, and that his guilt prevented him from accepting the treatment. It was suggested that the guilt would be explored and understood in the course of treatment, but this was unsuccessful in dealing with the resistance and referral was made.

This patient had come for treatment with intense guilt feelings over accepting money from his father. The guilt was compounded by accepting the treatment for free. The absence of a solid therapeutic alliance precluded dealing with this overwhelming affect. A follow-up of his paid-for therapy revealed a lofty ego-ideal, intense shame, and guilt over his rage at his father for putting him in a subservient position.

Patient 2 illustrates the use of superficial guilt in the service of resistance against involvement in the treatment when the resistance is actually due to something else.

Case 2. The patient, a 24-year-old man, complained of anxiety and depression since serving in Viet Nam, where he felt "bothered" by the sexual promiscuity of many of his friends. He had had an acute anxiety attack when his wife met him at the airport on his return to the United States. Because of his chronic depression and dim view of life, his wife had left him 2 months prior to his seeking psychotherapy. The patient was the son of a rigid fundamentalist minister; his mother shared the father's rigidity. There was one younger brother, described as "single, drives a sports car, and chases all the girls." The patient had dated his wife-to-be from the age of 17 and married her several years later. He related no marital conflicts prior to his return from Viet Nam. The wife was described as a rather rigid "Christian" woman who was somewhat naïve.

The patient was felt to be neurotic, with an unconscious nuclear conflict of an adolescent type. He had a very rigid and archaic superego and had never really negotiated adolescence in terms of dating, sexual experimentation, and rebelling against his parents. A contract for twice-weekly insight psychotherapy was made.

One of his first resistances was expressed as a feeling that other patients were waiting to be seen, he knew the doctor was very busy, so why should the doctor take time to talk with him when he was paying nothing? The patient was feeling guilty about being seen for free. He also had a sexual identity conflict commonly seen in adolescents. He wanted to be independent, discount his parents' beliefs and mores, and have a peer group with which to identify. He appeared to fear becoming passive and dependent on the physician, yet actually desired this desperately. Even with the knowledge that these were the real conflicts, it was impossible to deal with the superficial resistance regarding the lack of a fee. The patient interrupted treatment prematurely.

Any premature interpretation of the above material would only have served to heighten the patient's resist-

ance and produce more anxiety. Paying a fee, regardless of its size, would have made his superficial resistance accessible and allowed exploration of deeper material.

The wish for oral gratification and affects resulting from frustration frequently underlie pathological character structure. To unwittingly gratify rather than analyze these needs is to shield from therapeutic inspection potentially crucial material. Patient 3 exemplifies this dynamic:

Case 3. This 28-year-old single man had been hospitalized for 40 days because of disabling phobic symptoms and severe anxiety. He was treated with psychotropic medication and psychotherapy, followed by 2 years of psychotherapy with a resident. The treatment was through the university service and he was charged a nominal fee.

The patient's major dynamic structure reflected concern with desertion at the age of 5 by his father, a career military officer. He was very angry at both parents, and felt they still "owed" him something. He used repression, denial, displacement, and isolation of affect as major defense mechanisms and defended against his anger in the transference by passivity, feeling that the therapist owed him something. This conflict soon manifested itself over the fee and its payment, and many treatment hours were devoted to this issue.

Therapy was interrupted when the resident finished the training program, and the patient applied to the VA clinic for further treatment. He stated that money and paying for his treatment had been a major issue in his previous psychotherapy, that the issue was not completely understood, and that he should continue to pay a fee. He thought he would feel guilty unless he were paying something for his treatment. He was referred to the university service and has continued in psychotherapy there.

That the patient was able to verbalize the conflict about money and his need to continue to work on this issue revealed that he had made considerable progress. More importantly, he had the ego strength to refuse the free treatment, even though he desperately wanted to be seen for free. If this patient had been seen initially for no fee, these issues would not have arisen as soon, and the bill and its meaning for him would have never become the focal point of treatment. In essence, his neurotic wish to receive what was "due him" would have been gratified and would not have become an intrapsychic conflict.

Patients with overt sexual identity problems have great difficulty with free psychotherapy. Patients 4 and 5 illustrate fantasies of nonfinancial demands being placed on them by the therapist in lieu of money.

Case 4. The patient, a 24-year-old man, complained of depression and had much chronic, free-floating anxiety as well as difficulties about sexual identity. While overseas in military service he had his first homosexual encounter, and upon returning to the United States had both heterosexual and homosexual experiences. His father was a sadistic alcoholic who had deserted the family when the patient was 4 years of age. The patient was the man of the house after his father's departure. As a teenager he worked to help support the family and he continued to feel an obligation to help support his mother and siblings.

Insight psychotherapy progressed well through some 35 hours. The first transference reactions were of a homosexual attachment to the therapist, defended against by promiscuous heterosexual acting out. When cautious interpretations of the acting out were made, the patient began to verbalize concerns about the therapist's investing time when there was no financial reward. The patient feared that the psychiatrist would make homosexual demands of him.

Although this fear was clearly a projection of the patient's unconscious wishes, it was difficult to deal with this material when the patient was paying no fee. One cannot readily tell a patient that he is an interesting case for training purposes and that he was one chosen from many who applied for treatment. If patient 4 had been paying an appropriate fee his resistance could have been dealt with easily. The same concern would have surfaced later, but hopefully at a time when more groundwork had been laid and at a more appropriate time for understanding and interpreting the difficulty.

Case 5. This patient was a 26-year-old single student who appeared at the university clinic asking for help with two problems. First, he was on academic probation because of low grades and severe difficulty in relating to teachers and peers. He had temper outbursts at instructors, called them "stupid," and insulted them. Secondly, he experienced severe anxiety around women, either fellow students or teachers. He would immediately make a sexual comment or pass at the woman; this behavior naturally led to difficulties in his peer relationships.

The patient's mother and father had had difficulty in their marriage for as long as he could remember. When he was 8 years old, they divorced, with the mother taking the patient and the father the older sister. He recalled that at the time of the divorce he felt he was "Mother's favorite." His mother remarried some 2 years after the divorce. At that time, the patient was seen by a psychiatrist, diagnosed as "hyperactive," and treated with methylphenidate, with a good response. The patient completed high school without difficulty, but when he later went into military service he began to experience severe anxiety when around women.

The patient was seen twice weekly on the university service. The fee was set at four dollars per hour, and he was seen for 6 months with very good progress. The main vehicle of the treatment was interpretation of dreams. The patient's object relations improved markedly and he began to make excellent grades.

At the end of 6 months the resident rotated to the outpatient clinic of the VA hospital. Since the patient was a veteran, there was no difficulty in the resident's continuing to see him at the VA, but the fee was necessarily dropped. Subsequently the patient did not report a dream for 2 months and began to question why the resident was so interested in continuing treatment when no fee was involved. He stated that somehow he had felt better, and seemed to work harder in therapy, when he was paying. After 2 months, he related a dream in which he was going to visit his father. The affect in the dream was one of disgust, and the patient had nausea and vomiting in the dream. He also began to experience nausea and vomiting prior to coming for his therapy hours. Unconscious homosexual concerns about the therapist's intentions had arisen in the treatment as a result of the fee's being stopped. This was a projection from the patient, but it arose

prematurely because of the lack of a fee. This resistance and concern could not be dealt with on a realistic level and led to the patient stopping the therapy prior to a satisfactory working through and termination.

DISCUSSION

Although Lorand (5), Lievano (6), and others reported success with nonpaying psychotherapy patients, the lack of a fee in psychotherapy typically leads to complications. We have both had experience in low-fee cases seen as a requirement of psychoanalytic training. In these cases, the absolute fee as such was not the major issue, as long as the patient was paying a fee that was both appropriate for his financial circumstances and resulted in some hardship.

When the patient is treated for no fee many artificial variables are introduced. The lack of a fee may mobilize shame or guilt, which may preclude the patient's becoming involved in therapy. Some patients may use the lack of a fee as a superficial resistance to avoid involvement; with others, the absence of a fee may unwittingly gratify passive receptive wishes so that a very important portion of the patient's psychopathology never causes conflicts. With still other patients, fantasies of sexual involvement with the therapist will become intense enough to preclude continuation of treatment.

It is suggested that for the purpose of teaching residents in psychiatry the techniques of insight psychotherapy, all patients should be charged a fee. Lack of such a fee introduces an artificial variable that complicates and clouds the issues in treatment. When the patient is charged, many issues will naturally arise in regard to the bill—but these issues can be dealt with—whereas the issue brought about by no fee cannot always be resolved.

BRIEF COMMUNICATIONS

Albinism and Schizophreniform Psychosis: A Pedigree Study

BY MIRON BARON, M.D.

The author presents a pedigree study of albinism associated with schizophreniform psychosis and concludes that the evidence of an association between the two traits is strong; the evidence for genetic linkage is suggestive. The pineal hormone melatonin and the melanocyte-stimulating hormone inhibitory factor may be etiologic determinants of psychosis associated with albinism.

GENETIC LINKAGE studies have recently been of much interest in psychiatric research. Color blindness (1–3) and the Xg blood group (3–5) have been claimed to assort with bipolar affective disorder in a linked fashion. A possible involvement of chromosomal markers in the transmission of schizophrenic disorders has not to my knowledge been explored.

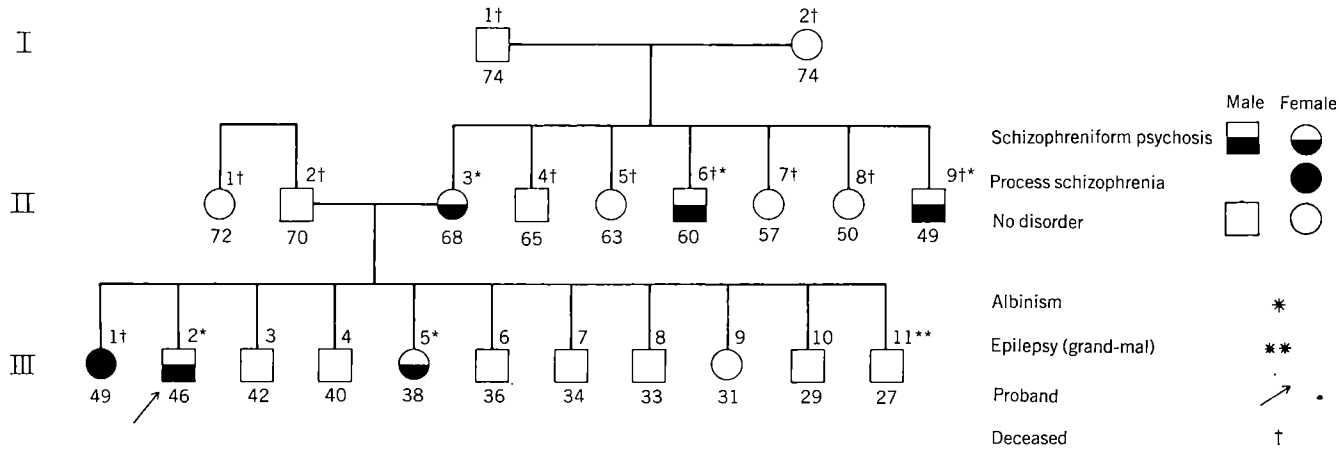
The present study was designed to test the hypothesis of a genetic link between oculocutaneous albinism and schizophreniform psychosis. I will also propose that a neurochemical defect in albinism may have played an etiologic role in the generation of psychoses in this pedigree. (This hypothesis would not necessarily require the existence of a specific gene for schizophrenia.)

DESCRIPTION OF THE PEDIGREE

The family I will describe is of Yemenite-Jewish descent. All available family members (see figure 1, subjects III-2 through III-11 and II-3) were personally interviewed and old medical records were reviewed. Diagnostic criteria for psychiatric disorders followed Feighner and associates (6) and Spitzer and associates (7). Albinism was detected by a general physical examination and/or information obtained from family members. The criteria for determining oculocutaneous albinism (8) included whiteness of skin and hair, reddish irides, and red pupils. Subjects III-2, III-5, and II-3 manifested photophobia, horizontal nystagmus, and myopia. Skin tyrosinase was not tested.

Psychiatric diagnoses for available subjects were determined by two independent raters. In order to minimize bias, psychopathology in deceased family members was assessed before their albinism status was established.

Personal interviews and record review permitted an adequate determination of clinical status in generation III and in subject II-3. Interviews conducted with all available subjects provided sufficient, although less comprehensive, data on probands' relatives who were dead at the time the study was done (generations I and II, excluding subject II-3). The sample included 22 subjects (figure 1.). All albino subjects assorted for schizophreniform psychosis (5 cases) and one nonalbino (subject III-1) manifested "core schizophrenia." Subjects II-3, II-6, II-9, III-2, and III-5 presented with clinical features compatible with a remitting schizo-affective disorder, depressed type (7), as evidenced by a temporal relationship of schizophrenic and affective components. The deteriorated illness course in subject III-1 was consistent with the diagnosis of chronic schizophrenia (7). It is worth noting that subject III-2 had been reared apart from age 3 by nonalbino, nonpsychotic parents before his illness onset, a finding that supports a genetic hypothesis.



DISCUSSION

Albinism is a genetically determined hypomelanosis (8) with a reported incidence of 1 per 10,000–20,000 (9). Photophobia, nystagmus, and defective vi-

Dr. Baron is a second-year resident, Department of Psychiatry, Albert Einstein College of Medicine, Bronx Municipal Hospital Center, Rousso Bldg., 1165 Morris Park Ave., Bronx, N.Y. 10461.

The author wishes to thank Drs. E.J. Sachar and E.S. Gershon for their criticism and encouragement and Drs. M.J. Stern and D. Dreifus of Tel-Aviv University Medical School for their clinical assessment and care of members of the pedigree.

FIGURE 1
Pedigree of a Family Assorted for Albinism and Schizophreniform Psychosis

sion may mark the clinical picture (8), and a frequent occurrence of hematological disorders has been reported (10, 11).

Genetic Hypothesis

Albinism is transmitted by an autosomal recessive gene. Thus, one can assume that subjects I-1 and I-2 (see figure 1) were both carriers. Because of the affected offspring in the third generation, one can assume that subject II-2 is heterozygous for this gene. Since the proportion of heterozygotes among nonalbinos is only approximately 1.4% (12), the possibility of a consanguineous mating must be raised. If one hypothesizes that psychosis is also being transmitted in an autosomal recessive fashion in the pedigree, one must assume that subject II-2 is also a carrier of a recessive gene for psychosis. Since the probability that a normal person is a carrier of recessive genes for both albinism and psychosis is even less than 1.4%, it seems even more likely that the mating is consanguineous. In fact, it might be argued that the probability of consanguinity in this pedigree is considerably higher than that in the general population because marital norms in isolated Yemenite-Jewish communities favor consanguineous mating. It is not essential, however, to know whether or not the mating is consanguineous in order to analyze the pedigree for an association between the two traits.

Guidelines for genetic linkage analysis have been presented elsewhere (12). The probability of linkage between genetic traits is a function of the distance between the two chromosomal loci carrying those traits. The closer the loci, the less likely it is that recombination (material exchange between paired chromosomes during the process of meiosis) will occur. Recombination between the two loci is denoted by the relative frequency of recombinants. Determination of the numbers of recombinants and nonrecombinants depends on the linkage phase in a doubly heterozygous parent in an informative mating. If one is testing the hypothesis that two recessive genes are linked (a gene for albinism and a gene for psychosis), a potentially informative mating is one in which one parent is doubly homozygous for the recessive genes and the other is doubly heterozygous. Subject II-3 is presumably doubly homozygous for recessive genes and subject II-2 is presumably doubly heterozygous. Since one does not know whether to hypothesize linkage in coupling or linkage in repulsion for subject II-2 (there was no information available on his parents to establish the nature of the assumed linkage), one cannot in fact determine which offspring are recombinants or nonrecombinants. (There are two possibilities: the schizophrenic albinos and normal offspring are recombinants and the schizophrenic nonalbinos are nonrecombinants and vice-versa.) Nonetheless, the ratio of nonrecombinants to recombinants or recombinants to nonrecombinants (the former, if one assumes linkage) is 10:1, which is suggestive of nonindependent assortment of genes. For linkage purposes, one has to assume that the genotype of subject II-2 is SsAa (s and a stand for recessive genes for schizophrenic psychosis and albinism, respectively) and that subject II-3 is ssaa. One must also assume that there is complete penetrance for ss genotype and that the Ss genotype is not affected.

The probability of obtaining a pedigree F1 if the hypothesis of linkage were true was compared with that of obtaining it under the hypothesis of no linkage, i.e., independent segregation. In the latter case, the recombination fraction Θ is ½. A maximum lod score Z, (the logarithm of odds favoring linkage over nonlinkage) was computed for $\Theta = .10$.

$$Z=\log\frac{P(F1|\Theta=.10)}{P(F1|\Theta=.50)}=1.55.$$

A Z score of 1.55 implies an odds ratio of 35.48:1 in favor of the hypothesis of linkage versus independence and may be considered suggestive of genetic linkage (12).

The offspring of subjects I-1 and I-2 should not be included in an analysis of nonrandom assortment of

genes, since it is impossible to determine which group of offspring constitutes a group of recombinants or nonrecombinants (noninformative mating). They can, however, be considered in an analysis of an association between the two traits, and the evidence is persuasive ($p < .001$, chi-square test, Yates' correction applied).

It can thus be concluded that the evidence for an association between genetically determined hypomelanosis (albinism) and schizophreniform psychosis in this pedigree is strong, but the evidence for linkage is merely suggestive. It could be argued, of course, that the albinos in this family might have been selectively mistreated and their subsequent development of psychoses was due to psychosocial rather than genetic causes. The development of psychosis in subject III-2, who was reared apart by nonalbino, nonpsychotic parents, presents crucial evidence against nongenetic transmission.

Neurochemical Proposition

Thus far, I have discussed my observation in terms of hypothesizing genetic linkage or a more general association of traits. I would now like to propose that a neurochemical defect associated with albinism might have played an etiologic role in the pathophysiology of schizophreniform psychoses. This hypothesis would not necessarily require a gene for psychosis and would not depend on genetic linkage.

Current biological models of schizophrenia postulate a γ-aminobutyric acid neuronal defect (13, 14) or dopaminergic hyperactivity in brain systems (15). The neurochemical hypothesis I propose requires two assumptions: that albinos are subject to enhanced retinal photosensitivity; and that excessive illumination mediated by optic neural pathways might result in decreased γ-aminobutyric acid neuronal tonus and/or increased dopamine activity in mesolimbic and nigrostriatal systems implicated in the neuropathology of schizophrenia (16, 17). The first assumption is supported by evidence that melanin impedes photoconductivity (18) and by clinical data on photophobia in albinism (8). Experimental evidence for the second assumption is based on data indicating modulation of neuroendocrine functions by lighting conditions. Excessive illumination curtails secretion of melatonin and melanocyte-stimulating hormone (MSH) (19, 20). Research data consistently indicate that melatonin inhibits production of prolactin release inhibiting factor (PIF) (21) and that exposure to light leads to decreased prolactin release (22). The suppression of melatonin activity by lighting conditions is considered to have eliminated the mechanism that opposes the action of the MSH-inhibitory factor (MIF) (20, 23). There is ample evidence to suggest that PIF and MIF release reflects dopaminergic activity in mesolimbic (24, 25) and nigrostriatal (26, 27) pathways, and that melatonin induces γ-aminobutyric synthesis (28, 29). It thus appears that melatonin deficiency and "high PIF-MIF" conditions might produce biologic vulnerability to psychosis by leading to 1) lower than normal tonus of brain γ-aminobutyric acid systems, and 2) increase in dopaminergic activity in neuronal systems implicated in psychosis. Such reciprocity has been related to the generation of schizophrenia-like conditions (14, 16). The evidence supporting the hypothesis is preliminary and inconclusive. Therefore, at this stage the proposition I have presented is merely a speculation.

Anticholinergic Exacerbation of Phenothiazine-Induced Extrapyramidal Syndrome

BY MURRAY ALPERT, PH.D., FLORENCE DIAMOND, AND EDWARD M. LASKI, M.D., PH.D.

The authors used tremography to record the bilateral digital tremor of a patient showing extrapyramidal system effects in response to withdrawal from phenothiazines. They found that changes in the amplitude of tremor correlated with clinical ratings of extrapyramidal disturbance. Changes in the amplitude and in the spectrum of tremor were similar to the bipolar paradoxical changes seen during intoxication with an anticholinergic psychotogen.

PHARMACOTHERAPY OF SCHIZOPHRENIA involves a fairly high incidence of a number of patterns of extrapyramidal system side effects (1). The frequency and intensity of the early akathisic and dyskinetic syndromes may usually be reduced by the addition of anticholinergic medication or by a more gradual increase in the dose of antipsychotic medication. Later in the course of pharmacotherapy other related classes of the extrapyramidal syndrome (EPS) may occur. One is a possibly irreversible tardive dyskinesia involving stereotypy and characteristic involuntary motility of the oral region (2, 3). Several pathophysiological mechanisms have been proposed in the etiology of the EPS (4–6). Extensive exposure to high doses of neuroleptic drugs is thought to be a prerequisite for the development of this condition, although some cases following moderate exposure have been reported (7).

A second syndrome, involving akathisic and parkinsonian features and, perhaps, buccolingual involvement as well as gastric and autonomic signs, has been reported to occur with abrupt withdrawal of phenothiazines (8–10). Several investigators have implicated withdrawal from the adjunctive anticholinergic rather than the neuroleptic medication in the genesis of this condition (11). Their results suggest that discontinuation of combined phenothiazine and anticholinergic medication predisposed patients to withdrawal symptoms.

When a patient showing some of these withdrawal signs was admitted to the metabolic research unit at New York University-Bellevue Medical Center, we took the opportunity to track this patient's EPS during the course of the withdrawal process, using recordings of her digital tremor as well as clinical ratings of her EPS. Informed consent was obtained from the patient and her husband.

CASE REPORT

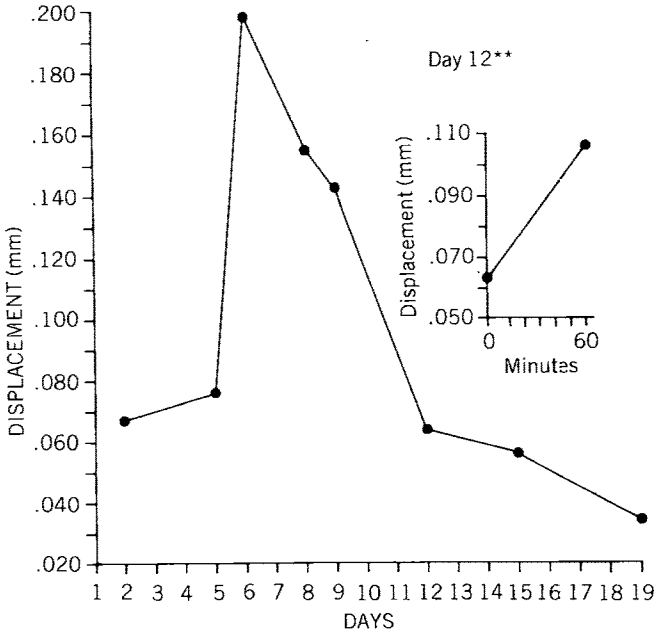
Case 1. M, a 39-year-old housewife who had been previously diagnosed as having manic-depressive psychosis, was admitted to the unit for special studies at Bellevue Psychiatric Hospital for observation and evaluation of her suitability for lithium treatment. Six months earlier she had been hospitalized because of changes in behavior characterized by excitability, hyperactivity, talkativeness, and manifest delusions and cognitive disturbances. She was treated with ECT and pharmacotherapy (150 mg of chlorpromazine twice a day in spansule form, 5 mg of trifluoperazine twice a day, and 2.5 mg of trihexyphenidyl twice a day). She had been taking this medication up to the day of her rehospitalization.

On admission she appeared ill, was markedly pale, physically weak, restless, apprehensive, and uncommunicative, showed no spontaneous speech, and revealed delusional thinking when questioned. There was a poverty of affect and evidence of extrapyramidal motor disturbance, including

Dr. Alpert is Professor, Ms. Diamond is Assistant Research Scientist, and Dr. Laski is Resident in Psychiatry, Millhauser Laboratory, Department of Psychiatry, New York University School of Medicine, 550 First Ave., New York, N.Y. 10016.

This work was supported by Alcohol, Drug Abuse, and Mental Health Administration grant MH-08618 from the National Institute of Mental Health and by a bequest from Elizabeth W. Bitker.

marked immobility and parkinsonian facies. A diagnosis of schizo-affective disorder with depression and drug-induced parkinsonism was made. All medication was stopped, and the patient was placed on placebo four times a day. A marked increase in the severity of the extrapyramidal disturbance, including cogwheel rigidity and tremor, was noted. Her gait became shuffling and unsteady, and her postural immobility and general flexion were more severe. For the next week the severity of extrapyramidal symptoms increased; they cleared during the following week.



Using methods previously described (12) we recorded this patient's bilateral digital tremor serially during the withdrawal period and more frequently during drug trials. The tremographic system provides a quantitative measure of the amplitude and spectrum of the displacement of the index fingers of each hand. The patient was also rated for the presence and severity of the EPS on a clinical rating scale patterned after that of Simpson and associates (13).

Figure 1 shows the average level of tremor for both hands during the period when the patient was demonstrating withdrawal. It can be seen that tremor amplitude increased for about a week and then gradually returned to the normal range during the next week. The amplitude measure is not simply a correlate for the clinical impression of tremulousness. Increased severity of the EPS, including such symptoms as rigidity, expression, and posture, are also reflected in the tremography. The correlation between the tremor amplitude and clinical measurements of passive stretch, cogwheeling, and tremor is highly significant ($r=.88$, $df=6$; $p<.005$). Tremor displacement is less strongly related to the total EPS rating score ($r=.66$, $df=6$; $p<.05$).

Initially the patient was receiving placebo four times a day. As the severity of her EPS increased (day 5), antiparkinson medication was initiated in divided doses (see figure 1). On three occasions (days 4, 7, and 12) tremor was recorded following administration of trihexyphenidyl. During a typical experiment (presented in figure 1 for day 12), tremor increased slightly for 30–60 minutes following oral ingestion of the drug and then returned to baseline or lower during the next several hours. This paradoxical increase in tremor following an antihistamine or anticholinergic appears to reflect the basic alteration in extrapyramidal organization of the withdrawal condition; it is not characteristic of the response to anticholinergic medication of either normal subjects or patients with Parkinson's disease.

Amplitude of displacement in the 1–2, 2–4, and 4–8 Hz bands was elevated initially, increased further, and then declined. These are the bands most sensitive to dyskinetic and parkinsonian effects. With initiation of anticholinergic medication on day 5, the 8–12 Hz band showed a marked increase and then a decrease as the extrapyramidal irritability cleared. This band has been less frequently implicated in pathological tremor, although we have previously noted increased amplitude here in tremulous states associated with alcohol withdrawal psychoses and with toxic doses of a psychotomimetic anticholinergic (14).

FIGURE 1
Average Right- and Left-Hand Displacement After Withdrawal from Neuroleptic Medication

*On day 6, 50 mg of diphenhydramine was administered intramuscularly twice. On day 5, 4 mg of trihexyphenidyl was administered; day 6, 6 mg; day 7, 4 mg; day 8, 10 mg; day 9, 5 mg; day 10, 7 mg; day 11, 2 mg; day 12, 4 mg; day 13, 4 mg; and day 14, 2 mg.
**This graph shows the patient's reaction to 2 mg of trihexyphenidyl on day 12.

DISCUSSION

Although we must be cautious in generalizing conclusions drawn from an individual patient, study of this case can contribute to the clarification of some of the issues related to phenothiazine withdrawal. The evidence indicates that our patient developed a reaction related to withdrawal from combined phenothiazine and antiparkinson therapy. Reinstitution of antiparkinson therapy in the absence of phenothiazines produced a paradoxical exacerbation of the extrapyramidal signs. During the course of the withdrawal episode changes in the amplitude of tremor correlated with clinical ratings of extrapyramidal disturbance, but the changes in the spectrum of tremor were similar to the bipolar paradoxical changes seen during intoxication with an anticholinergic psychotogen (14). This finding is in contrast to the spectral changes usually seen in dyskinetic disease.

In view of the reports that the extrapyramidal effects of neuroleptic medication respond favorably to institution of anticholinergic medication (15), the question arises as to why our patient showed an unfavorable response to diphenhydramine and trihexyphenidyl. The positive studies had been with con-

tinued phenothiazine therapy; therefore, it may be that simultaneous treatment with both classes of compound is required. The interactions between the two classes of compound in producing and resolving extrapyramidal effects have not been studied extensively; it may be that the combination of drugs has actions that cannot be predicted from their individual actions (16).

Over the years a number of lines of evidence have been interpreted as suggesting that basal ganglia activity can be best understood in terms of a balance between cholinergic and adrenergic transmitter systems rather than the level of activity of each system (17). Our results are consistent with the observation of Simpson and associates (11) that the withdrawal of the anticholinergic provokes the extrapyramidal syndrome, but the effect does not seem to result from the persistence of the more slowly excreted phenothiazines. Explanation of the idiosyncratic response shown by our patient and, perhaps, by the case reported by Moline (7) might best be sought in some special vulnerability shown by these individuals to alterations produced in central neurotransmitter metabolism by these psychotropic drugs.

Rapid Treatment of Acute Psychosis

BY WILLIAM H. ANDERSON, M.D., JOHN C. KUEHNLE, M.D., AND DONNA M. CATANZANO

Twenty-four patients with acute functional psychoses were treated with intramuscular haloperidol in a three-hour period. There was almost complete remission of cardinal symptoms (thought disorder, hallucinations, and delusional activity) in this period for 11 patients. Acute dystonia, easily reversed, was the only significant side effect. The authors therefore suggest that outpatient management may be feasible and preferable in the treatment of some acute psychotic episodes.

TREATMENT OF ACUTE psychotic episodes traditionally has included hospitalization and psychotherapy. In the past 20 years antipsychotic drugs have assumed a central role in the management of acute psychoses. That the so-called major tranquilizers have specific antipsychotic properties was recognized in the early 1960s by only a few authors (1, 2). Recent publications continue to emphasize the "tranquilizing" properties of these drugs rather than their ability to reverse more specific symptoms, such as thought disorders, hallucinations, and delusions (3, 4). Another recent report discussed the treatment of psychotic patients in a general medical setting, with an average length of stay of 9 days (5).

Although antipsychotic drugs are known to control violent and aggressive behavior, hypotensive side effects have discouraged their rapid administration (6, 7). Haloperidol, because it decreases α-adrenergic blockage, appears less likely to produce hypotensive effects than comparable doses of less potent drugs such as chlorpromazine (8, 9). Moderate doses of intramuscular haloperidol safely and effectively tranquilize acutely psychotic patients (10).

Hamill and Fontana (11) recently reported that chlorpromazine in doses up to 400–500 mg was ineffective in terms of both tranquilizing and antipsychotic activity in periods up to 5 days, a finding that contrasts sharply with earlier work (3, 8–10). Their research design used gradual increases of medication instead of the "digitalization" model described by Donlon and Tupin (10), in which high initial doses are quickly followed by low maintenance doses.

The question of dose-response and time-response curves for antipsychotic drugs is of current interest. Reversal of specific psychotic symptoms such as thought disorder in very short periods has not to our knowledge been reported yet. Such a finding would demonstrate the feasibility of ambulatory treatment or very short-term hospitalization for acute psychosis.

METHOD

The subjects were 24 patients who presented to the Acute Psychiatric Service of Massachusetts General Hospital with acute psychoses (onset less than 8 weeks) that met Research Diagnostic Criteria (12) for schizophrenia or mania. Patients with concomitant serious medical illness, epilepsy, or organic brain disease were excluded, as were women thought to be pregnant and patients in alcohol withdrawal. Patients who showed evidence of recent use of street drugs in history or physical examination were also excluded. Written informed consent was obtained from all patients prior to the research interviews and the administration of medication.

Patients were assigned randomly to two treatment groups. Both groups were initially given 5 mg of haloperidol intramuscularly. The high-dose group was then treated with 10 mg of haloperidol every 30 minutes until satisfactory remission of symptoms occurred or a maximum of 55 mg had been given. The moderate-dose group was treated with a dosage schedule of 5 mg of haloperidol hourly for up to 2 hours or until remission occurred.

All patients were evaluated hourly by a research analyst (D.M.C.) who was blind to the group assignment and treatment. Standard measurements were made using the Brief Psychiatric Rating Scale (BPRS). Interrater reliability between the research analyst and a senior clinician (J.C.K.) was established on another group of psychotic patients; coefficients were 0.72 for total BPRS and 0.86 for psychotic indicators.

The BPRS consists of 18 items reflecting mental status on a scale of 1 (not present) through 7 (extremely severe). Psychotic indicators within the scale consist of 6 items: conceptual disorganization, grandiosity, suspiciousness, hallucinatory behavior, unusual thought content, and elevated mood. Adverse reac-

Drs. Anderson and Kuehnle are Assistant Professors of Psychiatry, Harvard Medical School, Boston, Mass. Dr. Anderson is also Assistant Psychiatrist, Massachusetts General Hospital, Fruit St., Boston, Mass. 02114, where Ms. Catanzano is Research Analyst. Dr. Kuehnle is Assistant Psychiatrist, McLean Hospital, Belmont, Mass.

tions were monitored by a standard side-effects questionnaire (13).

After the initial 3-hour treatment period, patients were observed for 24 hours. Those judged to require further inpatient treatment were admitted to psychiatric facilities. Those whose clinical condition warranted outpatient treatment and who had adequate family and social support were followed in the outpatient service. Dosages and choice of medication were individually adjusted thereafter by clinicians assuming ongoing follow-up care.

RESULTS

The effect of the rapid intramuscular administration of haloperidol to these patients with acute psychoses is summarized in table 1. A patient was considered markedly improved if his BPRS score was 30 or less. This value was chosen as indicative of almost complete remission of symptoms and represents a mild level of disturbance typically encountered in outpatients.

Eight of the 19 patients who completed the protocol were given the diagnosis of acute schizophrenia and 11 were given the diagnosis of mania. There was no evidence of differential response to treatment on the basis of diagnosis.

No statistically significant differences in BPRS scores were noted between the high- and moderate-dose groups, who received average total doses of 33 mg and 13 mg, respectively, in the 3-hour period. The groups were then combined and the data were analyzed for dose response. The experimental design permitted patients to receive 5, 10, 15, 25, 35, 45, or 55 mg of haloperidol. Of the 11 patients who achieved satisfactory remission in 3 hours, 5 received 15 mg, 3 received 35 mg, and 1 each received 10, 25, and 45 mg. Thus there was wide individual variation in dosage requirements.

It is of greater interest that, in contrast to previous reports, substantial improvement was seen in short periods of time. In our sample of 24 acutely psychotic patients, 11 achieved marked improvement in 3 hours and another 5 within 72 hours. Moreover, this improvement consisted not only of the calming of anxiety or other nonspecific symptoms but also of amelioration of "core" psychotic indicators (hallucinations, unusual thought content, suspiciousness, elevated mood, conceptual disorganization, and grandiosity).

Adverse Reactions

Side effects were moderate or mild and in no case required termination of the protocol. There were no significant differences between high- and moderate-dose groups in incidence of side effects. The side effects that were evaluated are listed below.

1. Extrapyramidal reactions. Eight patients (4 in each group) experienced extrapyramidal symptoms, typically cervical and facial dystonia. All were treated with 2 mg of benztropine intramuscularly followed by oral benztropine as necessary.

2. Blurred vision. Four patients (2 in each group) complained of transient blurred vision. Two of them had received benztropine.

3. Dizziness. One patient (high-dose group) experienced transient dizziness without hypotension.

4. Possible hypotension. One patient (high-dose group) experienced transient faintness and pallor upon arising from a recumbent position. Blood pressure taken immediately thereafter in the recumbent position was 120/60.

5. Drowsiness. Six patients in the high-dose group (43%) and 2 in the moderate dose group (20%) experienced mild drowsiness at some point in the acute treatment phase. None of them was sedated to a point that would compromise the standard interviewing procedure.

TABLE 1
Response of Acutely Psychotic Patients to Intramuscularly Administered Haloperidol

Response Measure	Group: Moderate Dose (N=10)	Group: High Dose (N=14)	Total
Mean BPRS scores			
Pretreatment	66	57	—
After 3 hours	33	33	—
After 72 hours	28	27	—
Patient response (number)			
Marked improvement in 3 hours*	4	7	11
Marked improvement in 72 hours*	1	4	5
Improvement in 72 hours**	2	1	3
Unimproved	0	0	0
Dropouts***	3	2	5

* BPRS scores were 30 or less.
** BPRS scores were lower but still above 30; average reduction = 40.
*** Of the 5 dropouts, 3 withdrew informed consent for the research study but remained in treatment and did well, 1 eloped from treatment, and 1 could not be measured due to muteness, but did well in 1 week.

CASE REPORT

The following is an example of a case in which marked improvement was noted within 3 hours after administration of haloperidol was started.

A 38-year-old separated woman with a 2-week history of marked and rapid mood swings with anger, irritability, and elation came to the Acute Psychiatric Service in the company of her mother. She had not slept for 3 days. Two years previously she had had 3 hospitalizations, with the diagnosis of psychotic depression and, in the first hospitalization, sedative overdose. Mental status examination revealed that she was oriented but had inappropriate, elevated affect. Recent memory was intact. Stream of thought was markedly tangential. There was intermittent auditory hallucinatory activity and marked conceptual disorganization.

After she gave informed consent, the patient received 15

mg of haloperidol in a 2-hour period. Three hours after treatment began she showed some appropriate concern for her disturbance but her mental status was otherwise entirely clear. Her hallucinatory activity had disappeared, her stream of thought was no longer tangential, and her affect was not elevated or irritable. She experienced a dystonic reaction 7 hours after treatment began that was treated satisfactorily with benztropine.

On examination after 24 hours she maintained this remission in all details. She was placed on 25 mg of oral haloperidol daily and 1 mg of benztropine twice daily. She was followed by her local mental health clinic. Three months later her remission continued; the only medication she was receiving at that time was 50 mg of chlorpromazine at bedtime.

DISCUSSION

This preliminary study demonstrates the feasibility of bringing about rapid remission of acute psychosis: about half of our unselected cases were substantially relieved in a few hours. However, several important questions remain unanswered.

1. No drug-free control group was included. It is possible that some of the improvement resulted from nonpharmacologic factors. However, we think this is unlikely, since the value of chemotherapy in acute psychosis has been clearly demonstrated.

2. Even if we accept the feasibility of the rapid treatment approach, other clinical considerations need to be evaluated. It is possible that very rapid treatment may allow the patient or his family to deny the potential gravity of the illness and therefore become lax in continuing care. Clinicians should be especially aware of this potential pitfall in cases where a rapid and complete remission is induced.

3. When rapid remission occurs, prolonged hospitalization may be avoided and ongoing care may be given at a more convenient location. It is essential that the two care centers communicate the details of diagnosis, onset, and severity to ensure continuity of care.

4. The proper dosage and duration of medication following remission are still uncertain. There are undoubtedly many patients who may sustain a remission with little or no neuroleptic medication. How to identify such patients is an important research question.

These difficulties are present in the treatment of psychosis regardless of the method employed. Rapid remission is clearly no panacea, and, in fact, requires especially careful attention to details of diagnosis and continuing care. A safe means of rapid control of psychotic symptoms allows other therapeutic measures to be employed with maximum patient participation, economy, and avoidance of discomfort. Since it is clear that chemotherapy is not merely sedative but specifically antipsychotic, the patient deserves a chance for the rapid remission these drugs can effect.

Attitude of Psychiatric Residents Toward Patient Requests

BY SHERMAN EISENTHAL, PH.D., ROBERT FERRELL, M.D., AND AARON LAZARE, M.D.

The authors assessed residents' comfort in dealing with 14 previously identified types of patient requests in inpatient, outpatient, and acute service settings. First-year residents expressed significantly more discomfort than more experienced residents on 11 categories. They were also significantly less comfortable in the acute service than the inpatient setting. All residents expressed more comfort dealing with dynamic, psychological, and "nonsevere" requests. These findings suggest a need to teach residents specific therapeutic responses to various categories of requests and to evaluate the desirability of starting the residency experience on an acute service.

PATIENTS VERBALIZE many different kinds of requests for help when they come to a walk-in clinic. Systematic study of these requests, based on a series of factor analytic studies of patient endorsement of request items, has confirmed the presence of 14 request categories that fit into 2 broad classes, psychological and nonpsychological (1, 2). Nine psychological request categories have been identified: clarification, ventilation, control, confession, psychological expertise, psychodynamic insight, advice, reality, and succorance. The 5 nonpsychological requests are triage, medical, administrative, social intervention, and "nothing."

It is our contention that an understanding of these requests has particular value in the conduct of the initial interview. We believe the clinician should learn to hear and explore the request and then negotiate it with the patient in order to gain a sound diagnostic impression and design an effective treatment program. The rationale for this "customer approach" has been described in detail elsewhere (2). A recent study (3) found that a patient's satisfaction is more highly correlated with his belief that the clinician helped him verbalize his request than it is with feeling understood, feeling better, or even getting the disposition he wanted.

The clinicians who operate the Acute Psychiatry Service at Massachusetts General Hospital (also called the Walk-In Clinic) vary in their comfort in dealing with patient requests. Most of the clinicians are first-year residents in psychiatry who rotate in six-month shifts. The acute service is the first training site of residency for half of the residents; the other half start in the inpatient ward. Throughout all three years of residency, residents work in the outpatient psychiatry clinic, where they learn psychodynamics and individual and group therapy.

The source and nature of residents' discomfort with patients' requests have implications for training and clinical service. Such discomfort, whatever its source, could have a negative influence on the quality of interaction and outcome. We tested the hypotheses that the degree of comfort in dealing with patient requests would increase with level of training, vary with treatment setting. and vary with the perceived treatability of the patient, as indicated by a greater comfort with 1) psychological versus nonpsychological requests, 2) requests not associated with severe psychopathology, and 3) requests associated with dynamic treatment expectations, i.e., clarification and psychodynamic insight as opposed to advice, succorance, medical requests, or social intervention.

METHOD

A questionnaire was sent to all first-, second- and third-year psychiatric residents at Massachusetts General Hospital. Ten of the 12 first-year residents and 17 of the 25 second- and third-year residents responded. The residents received an envelope in their department mailbox containing the questionnaire, a cover letter, and a set of instructions. The letter explained the purpose of the research, gave an overview of the instructions, and indicated how the questionnaire was to be returned to the investigators. The residents were informed that the questionnaire would be given a code number to insure their anonymity.

The written instructions in the envelope asked the residents to rate their comfort in dealing with 84 patient requests in three treatment settings on a 6-point scale (very comfortable to very uncomfortable). The settings were the Acute Psychiatry Service, the outpatient psychiatry clinic, and the inpatient ward.

The questionnaire was adapted from the Patient

The authors are with the Department of Psychiatry, Harvard Medical School, Boston, Mass., where Dr. Eisenthal is Assistant Professor of Psychology, Dr. Ferrell is Clinical Instructor, and Dr. Lazare is Associate Professor. This work was supported by Alcohol, Drug Abuse, and Mental Health Administration grant MH-22922 from the National Institute of Mental Health.

Request Form (PRF), originally designed for administration to patients (1, 4). Factor analyses of the PRF items have provided considerable support for the 14 request categories deduced from clinical analyses and observation (1, 4).

RESULTS

Experience

The first-year residents had lower mean comfort scores than the second- and third-year residents on each of the 14 request categories. The differences (analyzed by t tests) were statistically significant for 11 of the 14 request categories ($p < .05$). There was a trend ($p < .10$) in two categories, clarification and social intervention, and no significant difference in only one category, triage. The first hypothesis, greater comfort with increasing experience, was thus strongly supported.

Setting

Comfort ratings for first-year residents differed significantly (by analysis of variance) among the three treatment settings on 11 of the 14 request categories ($p < .01$ in 4 cases and $p < .05$ in 7 cases). The three categories with nonsignificant differences were psychological expertise, clarification, and "nothing." The second hypothesis, that comfort varies with treatment setting, was thus also strongly supported.

We compared the comfort ratings of first-year residents in the inpatient and the acute service settings. In 10 of the 14 request categories, the ratings were significantly higher in the inpatient than the acute setting ($p < .01$ in most cases). However, the residents were more comfortable in dealing with triage on the acute service ($p < .01$).

Type of Request

The first-year residents were significantly more comfortable with requests that were psychological than nonpsychological ($p < .001$), "nonsevere" than "severe" ($p < .05$), and "dynamic" than "nondynamic" ($p < .001$). The preference of first-year residents for the dynamic requests (clarification and insight) was striking. The second- and third-year residents also showed the same pattern of significant differences with regard to these 3 types of requests.[1]

DISCUSSION

Our clinical observation that psychiatric residents describe varying degrees of comfort in dealing with patient requests was substantiated. The experience of the clinician, the treatment setting, and the type of request were all significantly related to comfort with requests.

[1]A more detailed presentation of the results is available from the authors on request.

The hypothesis that experience would influence comfort ratings was strongly supported. One source of the discomfort of inexperienced residents appears to be insecurity regarding skill and clinical judgment. First-year residents were uniformly uncomfortable with all categories of requests except clarification and triage. Triage (requests for referrals in the community) can be easily learned and places no emotional burden on the clinician. Requests for clarification allow the resident to rely on problem-solving skills previously gained in normal social interaction. Triage and clarification requests do not place a strong demand on psychiatric conceptualizing or treatment skills. The absence of experience and skill is most telling in the areas where special expertise, authoritative judgment, or active intervention are required or requested: psychological expertise (authority), succorance (demand for personal involvement and warmth), advice (demand for decision making), and reality contact and control (coping with more severe disorders).

Another important influence on the clinician's comfort is the treatment setting. One of our major findings was that residents were least comfortable dealing with patient requests on the acute service and most comfortable in the inpatient setting, almost without regard to type of request. It would thus appear that the effect of inexperience can be accentuated or reduced by the treatment setting—an interaction that is particularly important from the perspective of a training program. This finding is consistent with reports on the training experience in a psychiatric emergency room setting, which is recognized as a source of multiple demands and stresses for the beginning resident (5, 6). Steele (5) observed that the resident is required to be adept in using a variety of treatment procedures and to act with relatively incomplete information in dealing with patients who are usually severely disturbed.

The inpatient setting is relatively more conducive to comfort because there is less pressure to make quick decisions, greater and more sustained supervisory support, and more opportunity to correct mistakes and misjudgments. This salutary effect of the inpatient setting varied with the kind of request, but was especially evident for requests associated with severity of disorder. It made much less of a difference for requests that were dynamic.

This research raises the important question of the appropriateness of placing first-year residents in the acute service. If comfort were the crucial criterion, residents should receive their first-year training on inpatient wards, as is done in many training centers. However, ideological issues are also involved. Assigning first-year residents to the acute service obliges them, at a critical early stage in their professional development, to view patients from a much broader perspective than they would ordinarily gain working exclusively in an outpatient or inpatient setting (7, 8). It exposes them to "general psychiatry"; psychotherapy or an inpatient experience may be seen as psychiatric subspecialties (7, 9). Residents who start their training

on an acute service will require, partly because of the discomfort they will feel, far more supervisory and didactic input than either of the two alternative settings. A department that elects a first-year experience on an acute service must be prepared to pay this price.

There are factors other than experience and setting that affect the comfort ratings of first-year residents. Some of these are related to issues of identity, values, and ideology. If the discomfort in dealing with nonpsychological requests (e.g., medical, social intervention, and administrative) resulted from a lack of previous experience with such requests in a medical setting, then there should also have been discomfort related to requests for psychodynamic insight. In fact, residents felt relatively comfortable dealing with insight requests, which suggests that value and identity factors as well as a skill differential are involved. Becoming a psychiatrist, for many residents, means learning to be an effective dynamic psychotherapist. Dealing with dynamic requests thus fits residents' image of "psychiatry," while dealing with nonpsychological requests does not. We conclude that first-year residents are more receptive and comfortable with dynamic requests as a result of the process of identity formation (10–12).

Administrative and social requests appear to place the greatest strain on the psychiatric resident's conception of how to play the physician role. Morrison and associates (13) argue that residents must abandon the authoritarian physician role and interact from a peer-mediator perspective. Past training has oriented the resident to view the patient from the perspective of individual psychopathology (10) rather than that of the social network in which the individual is embedded. This traditional orientation does not prepare the resident to deal with a social system over which he has less control than he has over the individual patient. The administrative and social intervention requests press the residents to be involved with the social system. The resident may be required to intervene on the patient's behalf as advocate or initiator when the patient's resources are deficient or are unavailable due to emotional crisis. Such acts as making a telephone call to a relative, speaking to another physician or care-giving agency, or writing on the patient's behalf to a draft board are often seen by the resident as demeaning and self-effacing, making the resident feel that he is a possible target for criticism because he has diluted and diminished his professional role (10, 11).

The greater discomfort with nonpsychological, "severe," and nondynamic requests can be further understood in the following ways. First, many of these requests place greater burdens of work and responsibility on the clinician, regardless of experience, setting, and ideology. If an intervention request is appropriate, the clinician may have to call in the family. If a control request is appropriate, the clinician may have to arrange for hospitalization or provide frequent visits over the next few days. On the other hand, triage, which had a very high comfort score, represents a quick disposition with no further responsibility. Second, there is no systematic body of knowledge about therapeutic responses to many of these requests, such as succorance, expertise, and advice. We believe that conceptualizing the patient as having one or more clearly defined and easily recognizable requests makes it possible to develop therapeutic strategies or responses for each request. This becomes an important task if we assume that general outpatient care goes beyond providing insight and clarification. Presumably, we could lower residents' levels of discomfort by teaching them therapeutic responses to specific types of requests.

CONCLUSIONS

We have established that residents experience varying degrees of comfort in dealing with patient requests and discussed the clinical antecedents that may give rise to this discomfort. The fundamental question that remains is the impact of such discomfort on the clinical process.

Our impression (which requires further study), based on observation of live and taped interviews and on preliminary studies, is that a resident's discomfort may lead to avoidance, disruption, and distortion in evaluation of the patient's complaints and in the negotiation of a treatment plan. Patient dissatisfaction and lack of compliance are likely outcomes.

Treatment of Excessive Weight Gain in Patients Taking Lithium

BY G. MICHAEL DEMPSEY, M.D., DAVID L. DUNNER, M.D., RONALD R. FIEVE, M.D., TIBOR FARKAS, M.D., AND JULIA WONG

Six female primary affective disorder patients who had gained an average of 9.5 kg while taking lithium lost an average of 2.9 kg on a 10-day 900 calorie a day hospital diet containing 100 mEq of sodium per day. No evidence of lithium toxicity was observed on this regimen. There was no evidence that fluid retention played a major role in the weight gain.

SCHOU AND ASSOCIATES (1) reported weight gain of more than 5 kg in 11% of patients treated with lithium for a year or more and noted that weight reduction was difficult for these patients. According to our observations, approximately one-third of the patients attending the lithium clinic at the New York State Psychiatric Institute have experienced weight gain during chronic lithium prophylaxis. Several of these patients have complained of excessive weight gain ranging from 5 to 15 kg. In general, these patients have done well with lithium treatment, but they consider stopping the treatment in order to lose weight. They claim they have been unable to lose weight by dieting. On occasion, physicians have told these patients that amphetamines, diuretics, or thyroid medications might aid weight reduction.

Lithium discontinuance appears to be associated with a prompt return to the patient's prior frequency of affective episodes (2, 3). Thus these patients, mostly women, are faced with the choice of being overweight and affectively stabilized with lithium or losing weight and becoming depressed on manic again without lithium. The purpose of this paper is to report a safe and effective weight-loss regimen for patients who have gained weight during chronic lithium treatment.

METHOD

Six euthymic female patients with persistent complaints of excessive weight gain and inability to lose weight on self-regulated diets were admitted to the New York State Psychiatric Institute metabolic research ward and were placed on a calorie-restricted, sodium-, potassium-, and fluid-balanced diet. All patients volunteered for this 10-day study and gave informed consent for all research procedures. All of the patients had primary affective disorder (4); 5 were bipolar and 1 was unipolar. This ratio of bipolar to unipolar patients is representative of our general lithium clinic population. Furthermore, although there is no fee for clinic services, the majority of patients are of middle-class backgrounds similar to a private practice population (5).

The diet on the metabolic unit was specially prepared under the direction of the unit dietitian. Food intake was restricted to 900 calories, and the diet was designed to provide adequate amounts of all essential vitamins and minerals. The diets contained approximately 10 mEq of sodium a day, supplemented with 1-g capsules of sodium chloride given five times daily, and 60 mEq of potassium a day (no supplemental potassium was given). The patients were allowed ad lib fluid the first 2 days; the daily fluid intake thereafter was regulated to equal the established amount. Thus the diet contained normal amounts of electrolytes, fluids, and essential nutrients, but calories were restricted. During the study patients had no exercise other than that provided by the sedentary ward milieu.

Lithium medication was continued in the same doses as before admission. Fluid intake and output records were kept, and 24-hour urine collections were made. Urine electrolyte concentrations of sodium, potassium, and lithium were assayed daily and serum electrolytes were measured twice a week. When possible, a 5-hour glucose tolerance test was done, and 24-hour urine 17-OH and ketosteroid assays were obtained. All patients had thyroid function (T_3, T_4) tests, as well as routine medical laboratory tests on admission. No other medications were given during the hospitalization except in the case of 1 patient, who was continued on chronic estrogen therapy.

RESULTS

All patients lost weight during their 10-day hospitalization (see table 1). Weight loss ranged from 2 to 3.8

The authors are with the New York State Psychiatric Institute, 722 West 168th St., New York, N.Y. 10032, where Dr. Dempsey is Research Psychiatrist, Dr. Dunner is Psychiatrist, Dr. Fieve is Chief of Psychiatric Research, Lithium Clinic and Metabolic Unit, Dr. Farkas is Psychiatrist, and Ms. Wong is Dietitian. Dr. Dempsey is also Instructor in Clinical Psychiatry, Columbia University College of Physicians and Surgeons, New York, N.Y., where Dr. Dunner is Assistant Professor of Clinical Psychiatry, Dr. Fieve is Professor of Clinical Psychiatry, and Dr. Farkas is Assistant Clinical Professor of Psychiatry.

TABLE 1
Weight Changes in Six Patients on Lithium Maintenance, in Kilograms

Patient	Age (Years)	Duration of Lithium Therapy (months)	Prelithium Weight	Maximum Weight Gain During Lithium Treatment	Weight Loss During Diet Protocol	Weight at Discharge	Weight at Follow-up	Length of Follow-up (months)
1	63	77	63.0	12.0	2.4	67.8	64.3	8.0
2	58	12	77.6	4.5	3.8	78.6	80.4	5.5
3	39	3	65.6	8.9	3.3	69.6	63.8	6.0
4	51	12	75.0	6.2	2.9	78.3	79.5	1.5
5	46	78	61.2	15.6	2.0	77.7	74.5	1.0
6	51	60	67.8	9.8	2.9	68.8	66.5	1.0

kg, with a mean of 3 kg. Serum lithium concentrations for the group ranged from 0.56 to 1.19 mEq/liter. None of the patients complained of nausea, diarrhea, trembling, or other lithium side effects during the study.

Laboratory data revealed that urine output was always several hundred milliliters less than intake, and no evidence of water diuresis was noted. Furthermore, none of the patients exhibited natriuresis or kaliuresis, and lithium excretion in the urine very closely approximated oral intake of lithium. No abnormalities were noted in the thyroid tests, glucose tolerance tests, or urinary steroid determinations. Follow-up was performed by means of clinic visits and telephone calls as of May 10, 1975. These follow-up data, presented in table 1, indicate that weight loss continued at home for some patients, particularly those who continued a calorie-restricted diet.

DISCUSSION

The mechanism underlying weight gain during lithium prophylaxis is not known. Demers and Heninger (6) reported pretibial edema in 9 consecutive patients with a history of manic-depressive illness who were started on lithium carbonate. The edema was restricted to the pretibial area and the associated weight gains were reported to be in the 2–3 pound (1–1½ kg) range. They found that the edema was associated with high sodium intake (173–246 mEq/day), was reversible with spironolactone (although urinary aldosterone was not elevated in these patients), and spontaneously remitted when lithium was discontinued.

Kerry and associates (7) reported weight gain in 8 long-term lithium responders (5 women and 3 men). All cases showed an initial, often large, weight gain after beginning lithium. The weight gain then ceased and the weight remained constant at the higher level. Mood stabilization was concurrent with the weight stabilization, and Kerry and associates interpreted the weight gain as due to "improved general health and continued good appetite and diet of these individuals who are no longer suffering from recurrent attacks of severely debilitating illness." They felt that the increased weight was fat and "solid" tissue representing a "normal" weight rather than water retention, and they questioned the desirability of these patients dieting. Plenge and associates (8) have suggested that the weight gain seen in patients taking lithium may be due to effects of lithium on intermediary metabolism. They showed that lithium caused an increase in brain and diaphragm glycogen and a fall in liver glycogen similar to the effects produced by insulin (9). They found evidence that these changes were mediated by lithium-induced increase in plasma glucagonlike activity and increased liver phosphorylase *a* activity (10). In manic-depressive patients, however, Mellerup and associates (11) did not find an increase in plasma glucagonlike activity in those taking lithium. They did find that manic-depressive patients taking lithium had fasting plasma insulin values twice those of non-lithium-treated manic-depressive patients. Healthy control subjects had fasting plasma insulin levels similar to the manic-depressive patients taking lithium. Other workers have found insulinlike properties of lithium. Bhattacharya (12) found that lithium caused a decrease in blood glucose in intact rats and rabbits and an increased uptake of glucose in isolated diaphragm and epididymal fat pads of rats. DeFeudis (13) found that lithium caused an increased uptake of glucose in intact mouse brain. Plenge and associates (8) postulated that the effects of lithium on sugar metabolism would result in increased fat tissue formation in patients taking lithium. They were able to induce weight gain in lithium-treated rats that was 70% higher than that in sodium-treated rats and offered this as evidence that lithium by itself, independent of manic-depressive illness, causes weight gain in human patients.

Other workers have shown effects of lithium on intermediary metabolism—lipids in particular. Leal (14) found that lithium inhibits the incorporation of acetate into phospholipids and triglycerides in rats. Krulik and associates (15) found that lithium was associated with an increased incorporation of glucose into triglycerides and phospholipids in blood, liver, and brain. In fatty tissue, glucose conversion to phospholipids is increased but triglyceride synthesis is decreased, and the authors concluded that, overall, lithium inhibits

the utilization of glycerides for the synthesis of fatty tissue.

The treatment of weight gain due to lithium has not been formally studied or reported before this study, to our knowledge. Furlong (16) reported a single case of a 51-year-old female patient who developed signs of lithium toxicity 2 weeks after beginning a self-prescribed 1,000 calorie diet that was inferred to be low in sodium. Furlong's patient had previously been stabilized on 300 mg of lithium three times daily, and she successfully abated her diet-induced side effects by reducing the lithium dose to 300 mg twice daily.

Our study, which was conducted under conditions of rigorous metabolic control, showed that patients who have gained weight in the course of lithium prophylaxis can lose weight by diet alone, without resorting to amphetamines, diuretics, or thyroid supplements. Furthermore, this weight loss occurred without a specific exercise program.

We did not note any side effects like those reported by Furlong (16), probably because sodium and fluid intake were regulated at normal levels. Fluid intake and output records, along with urinary electrolyte data, suggest that the weight loss represented tissue rather than extracellular fluid. Weight loss continued or was maintained for those patients who stayed on the diet during the follow-up period, although the rate of weight loss was considerably less than that during their hospitalization, when strict adherence to caloric intake was observed.

In reviewing the courses of these 6 patients in the lithium clinic, it became apparent that this weight gain tended to occur in 1- to 2-month spurts that were concurrent with the short-term use of tricyclic antidepressants for mild to moderate depression.

Often, patients' weight continued to increase greatly after the antidepressants were stopped—when weight did decrease, it never reached previous lower levels. Further research should be devoted to the mechanism of weight gain during lithium treatment. Areas of interest include the relationship between thyroid function and lithium during weight gain, the relationship between administration of tricyclic antidepressants and weight gain, and the effect of lithium on appetite.

It should be noted that although these patients lost weight, 4 of the 6 did not achieve their prelithium weight during the 4-month follow-up period of this study. This was probably due to lack of adherence to the strict low-calorie diet regimen. However, once these patients were made aware of the fact that they could lose weight by dieting, they ceased complaining about their weight gain. We believe this study has wide applicability for clinicians who encounter significant numbers of patients being treated with lithium who complain of weight gain as a side effect. We consider strict diet an effective and preferable alternative to the use of medications such as diuretics, thyroid supplements, or amphetamines for weight loss.

In conclusion, patients who gain weight during chronic lithium treatment should be encouraged to lose weight by means of proper diet. Because electrolyte balance is important in the avoidance of lithium side effects, the physician should emphasize that weight loss can and should occur with normal salt (sodium) intake.

Treatment of Tricyclic Intoxication

BY RODRIGO A. MUNOZ, M.D.

The author outlines 11 supportive and symptom-specific measures for emergency treatment of intoxication with tricyclic antidepressants. He also describes 15 reported cases in which physostigmine was successfully used to treat tricyclic poisoning.

THE TREATMENT of tricyclic intoxication rightly falls in the realm of psychiatric studies because psychiatrists are prescribing the tricyclics in large amounts and for patients who are likely to use such drugs in suicide attempts. This paper discusses measures to be taken when tricyclic intoxication is suspected. They are addressed to the clinician who needs a plan of action that can be put into effect immediately.

EMERGENCY TREATMENT MEASURES

Treatment is both supportive of vital functions so that homeostasis is preserved and symptomatic for the specific effects of tricyclic antidepressants. Arena (1) proposed four cardinal principles of good management of poisoning: 1) identification of the drug or chemical as quickly as possible; 2) evacuation of the poison from the stomach, except when this is contraindicated; 3) administration of an antidote if one is available; and 4) symptomatic and supportive therapy as indicated. In an emergency situation the order of application of these principles may be altered depending on individual conditions. The following 11 steps are proposed for the psychiatrist seeing a patient in the emergency room when tricyclic intoxication is suspected.

1. Establish proper ventilation. Extension of the head and forward displacement of the mandible may help. If the patient is showing respiratory failure, the presence of an anesthesiologist for intubation and assisted respiration is recommended. Take vital signs and continue to record them according to the patient's condition. The patient's legs should be elevated to the level of the right auricle and the patient moved from side to side every 2 hours.

2. If the patient is alert, empty the stomach promptly by inducing emesis, followed by lavage if necessary. I usually administer 15 cc of syrup of ipecac, followed by large amounts of water. I start lavage in alert patients only if, in spite of the initial vomiting, the patient becomes progressively obtunded.

If the patient is confused or comatose I continue lavage for 24 hours or longer, depending on the apparent severity of intoxication. I use half-normal saline solution in repeated small amounts until the return solution is clear. Evidence that tricyclics are excreted in the stomach (2, 3) is the rationale for prolonged lavage.

3. Collect blood and the product of emesis for laboratory examination. This helps more in recognizing drugs than in evaluating the amount ingested, since blood levels of tricyclics are unreliable (4). If catheterization is indicated, urine obtained by this method should be sent to the laboratory for drug screening.

4. If the patient is no longer alert, is drifting into coma, or is already comatose, start 5% glucose in normal saline intravenously. Initially give 300 cc per hour; this may later be decreased to 200 cc per hour.

5. Obtain samples of all medications that the patient may have been taking at home, especially those likely to be used in a suicide attempt.

6. If the patient is comatose, install an indwelling Foley catheter.

7. If the patient has changes in consciousness or cardiac functioning, obtain an EKG. Barnes and associates (5) indicated that electrocardiographic tracings in patients poisoned with imipramine or amitriptyline show varying arrhythmias and/or widening of the QRS complex with S-T shifts. The widened QRS complex is often associated with a marked shift of the S-T segment, which gives the impression of extensive intraventricular block or ventricular tachycardia. Such EKG alterations should arouse suspicion of severe imipramine or amitriptyline poisoning. After the acute crisis is over, use of the stethoscope can replace EKG monitoring.

8. Minimize external stimulation to reduce the tendency for convulsions to occur. I presently use 10 mg of diazepam (Valium) intravenously for convulsions.

9. If hyperpyrexia becomes manifest, use ice packs and cooling sponge baths.

10. Shock, if present, should be treated by an internist, who can decide if intravenous fluids, oxygen, and corticosteroids are needed. If the use of digitalis is considered, the psychiatrist should alert the internist about the danger of increasing conduction abnormalities and causing greater irritation of the myocardium.

11. Use physostigmine for cardiovascular and central nervous system effects (6). Cardiovascular mani-

Dr. Munoz is in private practice in Sheboygan, Wis. Address reprint requests to him at the Medical Arts Building, 1226 North 8th St., Sheboygan, Wis. 53081.

festations include atrial tachycardia, nodal tachycardia, atrioventricular block, asystolic hypotension, intraventricular conduction delays, myocardial damage, and congestive heart failure. Central nervous system effects include agitation, hallucinations, extrapyramidal signs, seizures, and coma. Burks and associates (7) also mentioned choreoathetosis and myoclonus. These serious disorders have been attributed to the anticholinergic action of tricyclics. Several authors (8–12) consider physostigmine the logical antidote for tricyclic poisoning.

PHYSOSTIGMINE TREATMENT

I will discuss here 15 reported cases of successful physostigmine treatment for tricyclic ingestion. There is a growing literature showing that physostigmine is useful in the treatment of intoxication with any drugs producing a central anticholinergic effect.

As shown in table 1, serious effects have been detected with doses as small as 150 mg. Heiser and Wilbert (11) reported on a 53-year-old man who became disoriented and confused while taking 50 mg of amitriptyline three times a day and lithium carbonate. This patient improved after treatment with 2 mg of physostigmine given intramuscularly.

The most dramatic case, reported by Burks and associates (7), was that of a 2½-year-old, previously healthy child who took 400 mg of imipramine. He initially received 1.5 mg of physostigmine in 10 minutes, followed by 1 mg 30 minutes later, and then the same dosage 26 times in a period of 14 hours.

The largest overdose I am aware of was also reported by Burks and associates (7). Their patient took 10,000 mg of amitriptyline and responded well to 6 mg of physostigmine initially, followed by 2 mg 4 hours later.

My 27-year-old patient (14) took 9,850 mg of tricyclic antidepressants, which is the largest overdose I have successfully treated. She received 5–10 mg of physostigmine intravenously slowly every time she went into ventricular tachycardia. This patient was treated with 74 mg of physostigmine in the course of 6 hours.

The wide range of dosages reported so far by different clinicians indicates that each of them used physostigmine as a symptomatic treatment according to the patient's clinical condition, regardless of age (the second largest amount of physostigmine was given to a 2½-year-old child) or known amount of medication ingested. This point should be stressed because information given by the patient, examination of medication containers, reports by witnesses, and blood levels of the tricyclics are not fully reliable as guidelines for treatment.

Newton (4) warned about physostigmine-induced convulsions, which seem to occur after rapid intravenous administration. Rumack and Ott stated that they "have now had experience with well over 700 patients who have had anticholinergic findings treated with physostigmine. The results are truly dramatic. The side effects are minimal providing a rapid bolus of physostigmine is not given intravenously. Theoretically the drug is contraindicated in asthmatic patients, although we have used it in a few such instances with good results and without precipitating asthmatic attacks" (15).

TABLE 1
Characteristics of 15 Cases of Tricyclic Intoxication Treated with Physostigmine*

Study	Age of Patient	Amount of Tricyclics Taken	Physostigmine Dosage
Falletta and associates (9)	27 months	Not reported	1.0 mg/m²
Slovis and associates (6)	22 years	1,500 mg	3 mg
	16 years	1,500 mg	2 mg
	2.5 years	225 mg	1 mg
	29 years	900 mg	1 mg
Rumack (10)	14 years	Unknown	6 mg
Burks and associates (7)	2.5 years	400 mg	28.5 mg
	36 years	10,000 mg	8 mg
Heiser and Wilbert (11)	46 years	925 mg	2 mg
	53 years	150 mg	2 mg
Snyder and associates (12)	27 years	1,000 mg	8 mg
	32 years	1,000–1,500 m	16 mg
Granacher and Baldessarini (13)	32 years	625–750 mg	2 mg
	23 years	1,000 mg	2 mg
Munoz and Kuplic (14)	26 years	9,850 mg	74 mg

* Thirteen of the 15 patients experienced both central nervous system and cardiovascular symptoms; the second patient reported by Heiser and Wilbert (11) and the first patient described by Granacher and Baldessarini (13) had only central nervous system symptoms.

The Manfred S. Guttmacher Award

The American Psychiatric Association invites applications for its annual Manfred S. Guttmacher Award for 1977. The award is given for any outstanding contribution to the literature of forensic psychiatry in the form of a book, monograph, paper, or other work, including audio/visual presentations submitted to or presented at any professional meeting or published during the year ending December 31, 1976. The award, which includes an honorarium of $250 and a plaque, will be presented at the Convocation of Fellows at the Annual Meeting in May 1977, in Toronto, Canada.

Anyone who wishes may apply to receive the award by submitting five copies of the work as well as five abstracts to Carl P. Malmquist, M.D., Chairman, Guttmacher Award Board, 1700 18th Street, N.W., Washington, D.C., 20009. Entries will be acknowledged but will not be returned.

The deadline for submissions is January 1, 1977, and any entry to be considered must be in Washington by that date.

LETTERS TO THE EDITOR

Product Goals for Residency Programs

SIR: "The Educational Objectives of the Psychiatric Residency Program" by Joel Yager, M.D., and Robert O. Pasnau, M.D. (February 1976 issue) is a useful but incomplete step in the evaluation of psychiatric residency programs. It emphasizes process and cognitive objectives. I know of no residency program that currently specifies product goals.

Possible product goals for residents might include the following:

1. Restore 3 acute schizophrenic patients to social productivity within 18 months, as measured by a minimum annual income of $6,000.
2. Restore a minimum of 4 involutional psychotic patients to tax-paying status (if under age 60) within 6 months.
3. Restore 2 chronic alcoholics under the age of 50 to tax-paying status for at least 6 months, with no more than 6 absences from work within that time.
4. Preserve, through family and marital counseling, 2 marriages in imminent danger of divorce (where young children are involved).
5. Change 1 heroin addict to tax-paying status for a minimum of 6 months.
6. Change 1 student from dropout status to good academic performance (B average or better) for a minimum of 6 months.

It seems to be that emphasis on such clearly defined product goals would carry with it the need for acquisition of the cognitive and process skills Drs. Yager and Pasnau outlined. However, it is unlikely that many will accept the concept of product goals until residents and their supervisors are paid for their products rather than for process.

PAUL H. BLACHLY, M.D.
Portland, Ore.

Drs. Yager and Pasnau Reply

SIR: Dr. Blachly's point that product goals are ultimately more desirable than process goals in medical practice is well-taken. Thus far, the medical profession has made few attempts to define product goals for training.

Surgical specialties often require applicants for board certification to provide their operating records for review (although, to our knowledge, long-term follow-up is not part of that review). However, aside from current attention to medical audit and peer review, we are unaware of any medical specialties that link product outcome to certification. This may reflect an awareness of the limits of what the various branches of medicine, including psychiatry, can actually deliver. If oncology or neurology, to name but two other specialties, were to be financed on a product basis, the "product" would have to be defined in a very modest way or there would have to be a basic reassessment of societal values with respect to the economics of health care, so that the costs of the failures would be absorbed and borne by the few successes.

To link medical payments to successful outcome may imply that we are capable of a zero-error system of medical care, which is a desirable goal but is currently far beyond our means. Since we do not even know all of the variables in the pathogenesis and outcome of psychiatric problems—let alone how to control them—we are not yet in a position to provide guaranteed work, except in extremely limited ways.

Our own educational objectives for skills and cognitive mastery are the means that hopefully contribute to achieving the ends that Dr. Blachly seeks. Unfortunately, the state of our art is such that the relationship between the ends (how our patients do) and the means (the skills brought to bear by residents and their health care support systems) is too often obscure. We lack sufficient outcome studies to tell us what we can expect from good care as opposed to bad care or no care.

We can safely assume that several of the goals Dr. Blachly listed can be greatly influenced by many factors beyond a resident's control (e.g., patient motivation, quality of available ancillary services, and family, social, and economic situations). Thus, successful achievement of product goals does not necessarily ensure that a resident has mastered the skills and cognitive material. Product goals are not sufficient by themselves—some patients would improve (or worsen) regardless of the residents' abilities.

One caution in developing product goals is that they are frequently value laden, as are several of Dr. Blachley's. As Arnhoff (1) has noted, the rapid adoption of certain desired goals without adequate data about the ultimate effects of pursuing such goals may prove counterproductive in the long run. An example might be the rapid discharge of psychotic patients to families and communities that are ill equipped to receive them, which is a type of product goal.

Efforts have been made to avoid the difficulties presented by value-laden product goals, which cannot be generalized across different patient populations and treatment settings. One such attempt involved use of the goals-attainment method to establish expectations for a possible range of outcomes early in the course of the treatment of each individual case. Individually relevant outcome measures may thus be developed, and trainees can then be evaluated according to the outcome (2). It hardly needs to be said that goals should be mutually agreed upon by patient and therapist. Of course, here too the effect of outside influences on outcome cannot be controlled. However, in spite of methodological problems, such efforts may be useful in the development of practical, individualized product goals.

The question of what psychiatry can deliver is of paramount importance and needs to be researched. Where we can identify exactly how patients benefit from professional intervention and honestly link that improvement to the specifics of professional involvement, we can develop product goals for our trainees. While at present there are few areas in psychiatry that permit such statements to be made with con-

fidence, there are some to be noted. Hopefully the future will provide us with many more.

A Query on Follow-Up Results

SIR: J. Sanbourne Bockoven, M.D., and Harry C. Solomon, M.D., presented an interesting study of the outcome of treatment of patients in the Boston Psychopathic Hospital in 1947 and the Harry C. Solomon Mental Health Center in 1967 in "Comparison of Two Five-Year Follow-Up Studies: 1947 to 1952 and 1967 to 1972" (August 1975 issue).

The authors were surprised to find that 45% of the Boston Psychopathic patients compared to 31% of the Solomon Center patients had not been readmitted after 5 years, in spite of the fact that maintenance psychiatric drug treatment was used in the second study period but not in the first. This difference is highly significant according to my calculations ($p<.001$, chi-square test).

They attributed the difference to the aftercare program of Boston Psychopathic, but elsewhere in the article they stated that "no organized day program was available to patients discharged from Boston Psychopathic Hospital during the follow-up period. At Solomon Center, on the other hand, two types of day programs were available to discharged patients." Since the Solomon Center had a more elaborate and modern follow-up service, the results should have been better, not worse.

The authors stated that the two cohorts were about equal in severity of illness and resistance to treatment, although this is not supported by statistical data. There could be another explanation for this unexpected difference in follow-up results. It is probable that the methods of inpatient treatment in the two periods were different. Many patients in 1947 may have been treated with insulin coma or electroconvulsive therapy, whereas it is probable that insulin coma was not used in 1967 and ECT was used sparingly. It would be interesting to know whether these differences in inpatient treatment modalities were in fact present.

ROBERT B. DAVIS, D.P.M., F.R.C.P.
Bihar, India

Dr. Bockoven Replies

SIR: Dr. Davis has quite correctly surmised that the sample treated in the Boston Psychopathic Hospital in 1947 did include a rather large number of patients treated with ECT, insulin coma, or both. No patients were treated at the Solomon Center in 1967 with insulin coma, and only a handful were treated with ECT.

I should add that the Boston Psychopathic Hospital had no day program in 1947 or during the 5-year follow-up period, but it did provide extensive aftercare in the form of social casework by both social workers and student social workers, of whom there were considerable numbers.

We are most grateful to Dr. Davis for raising these points.

J. SANBOURNE BOCKOVEN, M.D.
Lowell, Mass.

More on Neuromuscular Side Effects of Antipsychotics

SIR: In his letter "Neuromuscular Side Effects of Antipsychotic Drugs" (January 1976 issue), Howard R. Barton, M.D., suggested that when a patient shows dyskinesia for months following cessation of neuroleptic therapy, "The proper approach would be to reduce the effective level of dopamine in pallidostriatal tissue. Amantadine has this effect on animal brain and should be more extensively studied as a possible approach to treatment of tardive dyskinesia . . ." In fact, amantadine has the opposite effect (1–3) and has been helpful in Parkinson's syndrome, where the lesion seems to be one of diminished dopamine availability (4, 5). Dr. Barton further states that the presence of tardive dyskinesia suggests cellular damage to the brain, which has not to my knowledge been conclusively proven (6).

While tardive dyskinesia remains one of the more perplexing and distressing problems of clinical psychopharmacology, answers and solutions are most likely to come from clear facts and documented data.

Boston, Mass.

Dr. Barton Replies

SIR: Dr. Gelenberg is quite correct in pointing out that amantadine is recognized as beneficial in Parkinson's syndrome, where the lesion seems to be one of diminished dopamine availability. Amantadine has been shown to cause an increase in dopamine release in the animal brain (1). This effect would probably increase the signs of tardive dyskinesia at first.

However, patients with Parkinsons's disease not uncommonly experience a fall-off of amantadine effectiveness after a few months (1). This indicates that increased turnover of dopamine has ultimately resulted in greater excretion of metabolic end products of dopamine. Hence, the functional

and storage pool of dopamine has now been effectively reduced in pallidostriatal tissue.

Under these circumstances, therapeutic effects would then reverse so that tardive dyskinesia would be ameliorated, but there would be no further benefit in terms of parkinsonian signs, which would have been replaced clinically by the dyskinesia as a natural process. This paradoxical effect, if confirmed in controlled double-blind clinical trials, would point further to the opposite neurophysiological natures of these two conditions.

Dr. Gelenberg further states that there is as yet no conclusive proof of cellular damage in tardive dyskinesia. Hollister (2) postulated that morphological damage to presynaptic membranes may occur, resulting in dopamine "leakage," which would create denervation supersensitivity to dopamine. At this point, dyskinesia may become severe and irreversible. (I had referred to this finding in my previous letter but the reference was unfortunately deleted.)

The presence or absence of specific brain cell damage in tardive dyskinesia needs to be determined. Neurohistopathologic studies of autopsy specimens of pallidostriatal tissue are suggested. Evidence should be sought for damage of the cell membrane of presynaptic axon terminals and postsynaptic nerve cell bodies.

Prolactin Secretion and Antipsychotic Efficacy

SIR: We are indebted to John M. Davis, M.D., for his timely overviews on maintenance therapy (December 1975 and January 1976 issues). Dr. Davis has again brought us up to date with "Recent Developments in the Drug Treatment of Schizophrenia" (February 1976 issue). In that paper, Dr. Davis reviewed clinical and animal experimental data on the recently introduced antipsychotic drugs molindone and loxapine, supporting the clinical efficacy of these agents as well as their properties for blocking dopamine activity, which are probably critical to their therapeutic efficacy.

We would suggest that neuroleptic-induced prolactin secretion in man be included in the evaluation of antidopaminergic properties of potentially efficacious antipsychotic drugs. This neuroendocrine test bridges the gap between animal data (such as neuroleptic blocking of amphetamine-induced sterotypy or apomorphine-induced emesis) and the much more crude and probably unreliable observation of extrapyramidal side effects in man. Since it appears that all currently available classes of antipsychotic drugs stimulate prolactin secretion by blocking its inhibition by dopamine (1), we did a study of the prolactin responses to molindone and loxapine in normal men.

In this study, a butterfly cannula was inserted in the arm vein of three resting subjects and blood samples were drawn every 15 minutes for half an hour before and 2 hours after oral administration of the test drug. Blood samples were analyzed for prolactin by radioimmunoassay (2).

The pertinent findings were that molindone and loxapine, like such representative antipsychotic drugs as chlorpromazine, butaperazine, thioridazine, and haloperidol, stimulated prolactin secretion. In each subject, prolactin concentration rose from a baseline of less than 8 ng/ml to a peak of 25 ng/ml or more in the second hour after drug administration.

Nonantipsychotic phenothiazines such as promethazine, as well as other types of psychotropic drugs without antischizophrenic properties (e.g., diazepam, amitriptyline, and lithium) did not stimulate prolactin secretion.

EDWARD J. SACHAR, M.D.
Bronx, N.Y.

Dr. Davis Replies

SIR: The information reported by Drs. Gruen and Sachar is an important addition to our knowledge on the mechanism of action of the antipsychotic drugs. With the addition of molindone and loxapine, which are the first drugs discovered in each of these two new classes of antipsychotics, there are now five classes of antipsychotic drugs that benefit schizophrenia. Evidence that these drugs also block dopamine receptors in man is provided by the fact that they cause extrapyramidal side effects and, more importantly, they stimulate secretion of prolactin, which is a hormonal marker for dopamine blockade. This provides evidence that a wide variety of antipsychotics have a hormonal effect in man consistent with dopamine blockade. Since it is unlikely that such structurally dissimilar drugs would share many common pharmacologic actions, this indicates that these drugs do block dopamine receptors in man, which is consistent with the hypothesis that the mechanism of their antipsychotic action lies in their dopamine-blocking properties.

More on Creativity

SIR: In his letter "Death, Creativity, and Depression" (April 1976 issue) Terry E. Passman, M.D., presented a theory of creativity along with some misstatements and misrepresentations about the state of research in the field. He refers to "one of the few 'facts' about creativity upon which all students agree, Henri Poincaré's four stages of the creative process—preparation, incubation, illumination, and verification." Poincaré described his own creative thought, but Graham Wallas (1) was the individual who described these particular four stages of the creative process and was the author of the terms. Although it is true that there is some general acceptance of Wallas' terms and description, based in part on a poorly designed study by Patrick (2), a later study by

Eindhoven and Vinacke (3) disproved the factuality of these phases.

Much of Dr. Passman's theory is a restatement of formulations presented more fully by other writers on creativity such as Harry B. Lee and Otto Rank. For some reason, many persons in our field tend to assume there has been little research on creativity and that they have been the first to present theories and hypotheses, but the 9,968 citations in my own two-volume bibliography of scientific writings on creativity (4, 5) belie this assumption.

ALBERT ROTHENBERG, M.D.
Farmington, Conn.

A Request

SIR: I recently saw in consultation an 81-year-old woman whose basic problems appear to stem from cerebral arteriosclerosis. Her husband told me he had read an article about a new type of medication that is being used to eliminate calcium deposits in the arterial tree. He did not remember the article and did not have a copy, but the notation he made leads me to believe that the medication he had in mind was cholestyramine.

He seemed to think that all I had to do was administer this medication once or twice and his wife would be able to get up out of bed and go back home and resume her duties. He told me that the article claimed over 4,000 people had been restored to normal activity as a result of having taken this particular medication.

Is cholestyramine being used for this purpose? If so, would someone write to me about its use, dosage, and the duration of treatment? Also, if some other drug is being used for this purpose, I would greatly appreciate learning about it.

A Behaviorist Omitted?

SIR: I think that "The Current Status of Behavioral Psychotherapy: Theory and Practice" by Isaac Marks, M.D., D.P.M. (March 1976 issue) was incomplete because the author failed to mention the important part Dr. Arnold Lazarus played in germinating and furthering behavioral psychotherapy (1).

The reference to other types of therapists using behavioral methods but labeling them as something else (e.g., Viktor Frankl's "existential logotherapy") could also be applied to behaviorists, who have, for example, renamed hypnotic techniques as relaxation, suggestion, fantasy, and imagery.

REFERENCE

1. Lazarus A: Behavior Therapy and Beyond. New York, McGraw-Hill, 1971

EDWARD M. SCOTT, PH.D.
Portland, Ore.

Dr. Marks Replies

SIR: Dr. Scott is quite right in calling to our attention the fact that Dr. Arnold Lazarus, along with other workers, had a seminal role in developing behavioral psychotherapy in its early years. Dr. Scott is again correct in noting that many methods of treatment which are now labeled behavioral were used with different labels in the past. Role rehearsal, role reversal, and even doubling, which are now a part of social skills training, have been used for half a century in psychodrama. There is hardly a behavioral technique that has not been used at some time in the past under some other name and with some other theoretical justification. The only difference, perhaps, is that when used in a behavioral context the methods tend to be more systematized and the outcome more carefully measured, although this is not always the case.

ISAAC MARKS, M.D., D.P.M.
London, England

On Prophylaxis in Unipolar Affective Disorder

SIR: We have reviewed the evidence for drug prophylaxis of affective disorders (1, 2) and wish to clarify what gaps remain in our knowledge about prophylaxis of unipolar manic-depressive illness.

We will define two types of prolonged treatment studies: continuation and prophylactic. Continuation studies involve continued use of an agent immediately after disappearance of acute symptoms for about six months, the rationale being that organic therapy suppresses depressive symptoms without curing them and the underlying pathophysiology continues to run its course. In prophylactic studies, treatment is instituted when the patient is euthymic, with the expectation that the medication will prevent future episodes. A continuation study becomes prophylactic at some point, usually arbitrarily defined as six months after remission.

Conclusions about the prophylaxis of unipolar illness will have sweeping public health implications. Lithium is clearly of value in preventing mania in bipolar manic-depressive illness. Evidence for lithium prophylaxis in unipolar patients is strongly suggestive, but firm conclusions are unwarranted. Morbidity and mortality from lithium will increase as it is prescribed for prolonged periods, away from academic centers, and with poor supervision and laboratory facilities. Therefore, lithium's efficacy and risk/benefit ratio should be well established before its long-term use becomes widespread. These data have not been collected.

In order to safely interpret data that are not derived from

prospective controlled studies, we must be able to predict the course of unipolar illness, which is not currently possible. One group has suggested that morbidity of affective illness increases with time (3), another that a period of well-being follows a series of affective exacerbations (4). Consequently, only data from prospective placebo-controlled studies employing random assignment should be used.

Only three of the six most frequently quoted studies in which the prophylactic effect of lithium was tested in unipolar patients (5–10) involved random assignment to placebo or lithium and were double-blind (6, 7, 10). Two were so-called mirror image studies (5, 8), and one was an open trial with a retrospective control group (9).

Another report (11) supported a prophylactic effect of lithium in unipolar patients; however, 9 bipolar II patients (with a history of hypomania), 7 patients rediagnosed as "chronically depressed," and 8 other patients were removed from the sample. It was subsequently reported that bipolar II patients (12) and "chronic depressives" did not demonstrate lithium prophylaxis of depression. The removal of 24 patients undermined the definitively prospective nature of the study.

The remaining prospective studies (6, 7, 10) included 113 patients, approximately 40 of whom were men. Thus our present knowledge about lithium prophylaxis is based on data from fewer than 40 women and 20 men who actually received lithium in controlled prospective studies. Statements based on these results require confirmation in further trials with placebo comparisons.

The design of the Baastrup and associates (6) placebo-controlled discontinuation study of patients who had been asymptomatic on lithium for a prolonged period limits the generalizability of their findings. Patients with continuing symptoms often become disenchanted and seek other forms of treatment; thus it is likely there was attrition of lithium nonresponders before the controlled portion of their study began. Therefore, their results may indicate only that lithium has a prophylactic effect for some unipolar patients; no identifying features of this subgroup other than previous successful lithium treatment are provided.

One could generalize from pooling the analyses of Coppen and associates (7) and Prien and associates (10) that lithium has a demonstrable prophylactic effect, but the p value would not be overwhelming and the estimate of effect size would not be very firm. It would be worthwhile to pursue this work to help estimate effect size and to identify the boundaries of the drug-sensitive population.

There is some evidence that the mode of inheritance of depression may be different in men and women (13), so there may also be sex-related characteristics with regard to treatment response. One must be cautious when generalizing therapeutic effect from female to male unipolar patients—too few men have been studied to draw any conclusions.

In summary, we believe that the utility of lithium in the prophylaxis of unipolar manic-depressive illness is strongly suggested but not proven by prospective random-assignment placebo-controlled studies. Although there is evidence from so-called mirror image studies (5, 8, 14), these data should not be used in the final decision about lithium's prophylactic effect in unipolar illness. The only controlled study (10) found a prophylactic effect of imipramine in unipolar patients.

At present, before prescribing a prophylactic regimen for a unipolar patient, the clinician must assess severity, risk, and the likelihood of achieving a prophylactic effect. We hope that further studies will clarify the probablility of prophylaxis as well as the role of antidepressants in the prophylaxis of recurrent depressive disorder.

Some Observations on Maintenance Therapy

SIR: I appreciated the two overviews by John M. Davis, M.D., in the December 1975 and January 1976 issues of the *Journal*. I believe the subject of maintenance therapy has not received the attention it warrants and has been accorded low prestige within the field of psychiatry.

While working on the staff of St. Elizabeths Hospital and in private practice, I have had 40 or 50 long-term maintenance patients, almost all schizophrenics in remission. They are outpatients who live and (in many cases) work in the community. They often ask about decreasing or stopping medication and I always discourage this request. My thinking is that the social cost of a relapse into psychosis is too high a risk.

After a patient discontinues the medication, it may be many months, perhaps a year or more, before a relapse occurs. This increases the chances that the patient and his/her family will have lost contact with me or any psychiatric treatment facility, which complicates the situation greatly. Another factor is that patients at the point of relapse are often extremely negative about resuming medication or getting back into psychiatric treatment of any kind. In my experience it is

extremely unusual for such a chronic schizophrenic to resume taking the medication as an outpatient and go into remission without rehospitalization. Rehospitalization is almost always necessary, often under traumatic circumstances. The greatest problem with this seems to be loss of employment or retirement on disability, which could have been avoided. I would also like to note that none of these patients has experienced serious side effects.

GARY SINGLETON, M.D.
Washington, D.C.

Psychiatry, Cafeteria-Style

SIR: I attended my first APA annual meeting this May in Miami Beach, and for a couple weeks after it I was in a state of agitated perplexity. Then I had a flash of insight that rendered the experience coherent and freed me from the fetters of my confusion. I realized that I had not really been at a convention but rather at a cafeteria.

For appetizers there were morning panels and discussion groups. The "main courses" consisted of collections of papers designed to provide a balanced meal and available in a toto or a la carte. "Full course" meals were available, i.e., a day's worth of digestibles that focused on a particular subject. There were snacks—films, video, special lectures—some gourmet, some greasy spoon. For dessert there were after dinner panels and groups—more food for thought. The play "Equus" was presented, perhaps as a cleansing purgative or emetic.

By and large, the food was cafeteria quality—filling, but often rather bland or pasty, and frequently lacking spice or condiments. It was prepared for the masses and too often provided sustenance rather than nourishment.

When one left the cafeteria, one could find no remedy in the environs for dyspepsia or other gastric distress. Miami Beach has become a seemingly endless stretch of stucco-coated extended care facilities masquerading as hotels. Obsequious, tip-hungry servants pester one like eager mosquitoes. Pavement has consumed the tropical splendor that once was, and coconut oil is to be found only in suntan lotion. Miami Beach has been denatured, and no additives, colorings, or preservatives can correct the blight of environmental poisoning.

I am left with several questions. I ponder about the price of this meal and who pays it. Is there a proper etiquette for dining with this professional fraternity? And I wonder, what does one do with the garbage?

LLOYD SEDERER, M.D.
Cooperstown, N.Y.

Preciseness in Diagnostic Terminology

SIR: I wish to draw your attention to an inaccuracy in "Hypothalamic Tumor Presenting as Anorexia Nervosa" by Geoffrey B. Heron, M.D., and Donald A. Johnston, M.D. (May 1976 issue). The title is incorrect; the patient they described did not suffer from anorexia nervosa but from ordinary loss of appetite with nausea and vomiting. Except for his weight loss, he presented none of the characteristic features of anorexia nervosa, which are pursuit of thinness, frantic preoccupation with weight and eating, hyperactivity, and efforts at independence. The diagnosis of anorexia nervosa should not be made on the basis of absence of an organic explanation for weight loss or of vague psychological disturbances in a patient's history. Confusion about the condition is perpetuated when such nonspecific cases of weight loss are reported as anorexia nervosa.

HILDE BRUCH, M.D.
Houston, Tex.

Diphenylhydantoin Treatment of Bulimia

SIR: Richard S. Green, M.D., and John H. Rau, Ph.D., described successful treatment with diphenylhydantoin of 10 patients with compulsive eating (April 1974 issue). We treated a patient with a similar problem unsuccessfully with that drug.

The patient was a 25-year-old woman with a history of anorexia nervosa that began at age 19. From a normal weight of 47.7 kg she dropped to a nadir of 28.1 kg when she was 22. At age 23 she began to have episodes of binge eating. Continued psychotherapy and treatment with amitriptyline had no effect. An EEG taken before diphenylhydantoin therapy was initiated was interpreted as mildly abnormal—like those of the patients described by Drs. Green and Rau—because of lower frequency forms in the temporal and frontal regions, more prominently on the right. At the time diphenylhydantoin was begun, the patient's weight was 65.9 kg. She was treated with 100 mg of diphenylhydantoin 4 times daily for 5 weeks. During the last 3 weeks of this period she was also off amitriptyline (she had been taking 50 mg at bedtime). There was no remission of her compulsive eating, and at the end of the 5 weeks her weight was 67.7 kg. Thus, the successful treatment described by Drs. Green and Rau was a failure in our similar patient.

THEODORE WEISS, M.D.
LEONARD LEVITZ, PH.D.
Philadelphia, Pa.

Cogwheel Rigidity Early in Lithium Therapy

SIR: Baron Shopsin, M.D., and Samuel Gershon, M.D., reported on "Cogwheel Rigidity Related to Lithium Maintenance" in the May 1975 issue of the *Journal*. Their observation of this side effect was in cases of long-term lithium maintenance therapy; I have seen cogwheel rigidity appear early in the course of lithium therapy.

The patient I would like to describe was a 19-year-old male with bipolar illness who presented in an acute manic state. He had never taken lithium before. He was started on 300 mg of lithium 3 times a day and the regimen was increased to 2100 mg/day over a 2-week period. By the end of the third week, his mood had stabilized and his serum lithium level was 0.8 mEq/liter.

A few days into the fourth week, the patient complained of muscular tightness (in contrast, the patients reported by Drs. Shopsin and Gershon were asymptomatic). Physical examination revealed coarse bilateral cogwheel rigidity that did not respond to intramuscular benztropine (4 mg) or intramuscular diphenhydramine (50 mg). There was no akathisia or festinating gait. The usual signs of lithium toxicity, such as fine tremor, polydipsia, and polyuria were not present. Mental status examination revealed no evidence of an organic mental syndrome.

The patient's serum lithium level, however, had increased from 0.8 to 1.6 mEq/liter over 48 hours. (The level was 1.4 mEq/liter when remeasured the next morning.) The cogwheeling persisted until the lithium dosage was reduced 24 hours later to 300 mg 4 times a day. Complete resolution of both the cogwheeling and the subjective muscular discomfort coincided with return to previous serum lithium levels.

The patient had also been taking up to 30 mg of thiothixene daily for 3 months, but this had been discontinued 1 week prior to the onset of the phenomena I have described, and there was no earlier history of extrapyramidal signs.

The correlation between the fluctuating levels of lithium and the course of the muscular symptomatology indicates that cogwheeling should be considered as a possible initial sign of lithium toxicity.

RALPH D. BIEN, M.D.
New Haven, Conn.

Drs. Shopsin and Gershon Reply

SIR: In our article, we reported benztropine-resistant extrapyramidal symptoms (EPS) in the form of cogwheel rigidity during maintenance treatment with lithium carbonate. These symptoms occurred in outpatients who had 8–12 hour lithium blood levels within the therapeutic range, had no other symptoms of lithium toxicity, and were receiving no other medication.

Branchey and associates (1) have since confirmed our findings of EPS in patients on long-term lithium maintenance. In addition to cogwheel rigidity, these authors also reported other signs of EPS, such as rigidity, tremor, and positive response to a glabellar tap. One of the many problems in evaluating this essentially confirmatory follow-up study is the issue of concomitant use of other drugs, e.g., tricyclic medications, as well as previous ingestion of neuroleptics within 6 months of testing. The possible drug synergism makes the relative contribution of lithium difficult to assess and detracts from the findings. We have previously indicated that

> lithium, by virtue of toxicity or other physical properties, does appear capable of modifying brain tissue, bringing about decreased threshold tolerance or sensitivity to other drugs (e.g. phenothiazines or tricyclic compounds), even those previously tolerated prior to lithium ingestion. (2, p. 116)

Also, in the report by Branchey and associates, antiparkinsonian drugs were not given (not indicated) and the precise duration of treatment is not given for lithium or the tricyclic drugs. The only data offered with regard to treatment duration support our previous impression of a relationship between cogwheel rigidity and the duration of treatment with lithium. (Patients with cogwheel rigidity had taken lithium for 2 or more years; range of treatment duration was 6 months to 7 years.)

The fact that Dr. Bien's patient was given thioxanthine (thiothixene) in doses of 30 mg/day for 3 months prior to lithium therapy makes it difficult to single out lithium as anything but contributory to such symptoms of cogwheel rigidity. It is well known that it may take up to 6 months after treatment with neuroleptics before all the drug and its metabolites are no longer traceable in the blood tissues. An extrapyramidal symptom often can be expected to occur rapidly after initiation of lithium treatment in such individuals (3).

We would like to point out that parkinsonism and other signs of extrapyramidal involvement, albeit not well known, have long since been reported as symptoms of CNS involvement with acute lithium toxicity and poisoning (3).

We wish to thank Dr. Bien for providing us with the opportunity to make these comments.

Corporate Inhumanity

SIR: I commend you on your Special Section, "Disaster at Buffalo Creek" (March 1976 issue), but I am troubled by its focus. James L. Titchener, M.D., and Frederic T. Kapp, M.D., wrote in "Family and Character Change at Buffalo Creek" that the disaster "was caused by the inexplicable inhumanity of a powerful corporation that gave terrible evidence of not caring about its employees or their community." Inexplicable to whom?

It is abundantly clear that corporate structure, like personality structure, reflects underlying energic relationships vis-à-vis the "external world." The raison d'être of corporate structure is the accumulation of profit; all other considerations pale beside this one. The aforementioned inhumanity is therefore a necessary condition of this structure, not an inexplicable aberration.

When the collected energies of a "body" (corporate or individual) are devoted to the attainment of one goal (money in this case), certain predictions can be made about the behavior of that body in peripheral areas. Such behavior will be characterized by aggressivity; there will be conscious and/or unconscious attempts at denial, isolation, doing-undoing, and the underlying wish structure will be permeated with fantasies of destruction and self-aggrandizement. One could also predict symptomatic expressions of this structure, and such predictions would be abundantly confirmed in the factories, mines, bureaucracies, etc., that this corporate organization oversees.

The disaster that occurred at Buffalo Creek is not inexplicable. What is inexplicable is that this grossly visible schema of operation, where the likelihood of profit is the only rationale for the expenditure of energy, remains largely unaddressed by psychiatrists, whose professional lives are filled with its casualties. Can we continue to remain silent on the systematic problem and focus only on its symptomatic expressions, e.g., the victims of Buffalo Creek?

Incidentally, I would like to know if the group of mental health workers at Buffalo Creek had the opportunity to interview the management of the coal company. I would imagine

that they too underwent adaptive psychological processes, including the formation of symptoms. It would be especially interesting to know what adaptive defenses were most utilized by this group and to try to answer the question, How do they continue to do what they do in the face of the overwhelming evidence of their own "inexplicable" inhumanity?

DONALD B. MOSS, M.D.
Brooklyn, N.Y.

Drs. Titchener and Kapp Reply

SIR: We agree with Dr. Moss that the use of the adjective "inexplicable" was ambiguous in our paper. We intended to indicate the disaster was not explicable to the survivors because they could not conceive of the inhumane and uncaring attitude of the mine owners who were also their employers in many cases.

Many large conglomerate businesses, because of diffuse ownership, absentee top management, and the varied and spread-out nature of their business activities, have little personal contact with the people they serve and also the people they employ. Many casualties occur in the middle-management executives of such conglomerates and the members of their families as well as in the ordinary workers.

Like Dr. Moss, we wonder whether profit is incentive enough to resolve the many complex psychological, economic, and political problems that face the nation and the world today. There are follow-up studies under way with the surviving victims of the disaster at Buffalo Creek so that we can learn about its long-range effect. The successful law suit may have had a restraining and moderating effect on the policies of mining companies in the Appalachian area. Only the future will tell.

A Program Problem?

SIR: Joel Yager, M.D., and Robert O. Pasnau, M.D., have made an important contribution to psychiatric education by attempting to clearly delineate the tasks and educational goals of residents at different stages in their training. However, the program they described in "The Educational Objectives of a Psychiatric Residency Program" (February 1976 issue) lacks any attention to an area that requires the learning of skills necessary for one to become a "complete" psychiatrist, i.e., community psychiatry.

I believe that by the end of the resident's training, he or she should have developed the skills necessary to become, in Cohen's words (1), a "collaborative co-professional." Nowhere in the Yager and Pasnau article do they give any attention to this issue. Cohen has outlined the roles and tasks, an outline I expanded (2), emphasizing the many skills of the resident as generalist as well as specialist. Drs. Yager and Pasnau neglected the following goals that can best be learned in a community psychiatry setting: administration, leadership and management skills, teaching and supervision of other coprofessionals, community and agency consultation, long-term treatment of the severely dysfunctional patient, and elements of geriatric psychiatry.

By adding these areas of proficiency to the outline proposed by Drs. Yager and Pasnau, the psychiatric residency training program may be considered to be relatively complete. Any trainee, of course, may elect to underutilize some aspects of the skills and knowledge gained anywhere along the way, but the opportunities to learn the skills must be present in all programs if the goal is, as I would hope, to produce competent general psychiatrists.

KENNETH SOLOMON, M.D.
Albany, N.Y.

Drs. Yager and Pasnau Reply

SIR: Dr. Solomon raises an interesting point regarding what he terms the lack of attention to an area required for one to become "a complete psychiatrist"—the area of community psychiatry. We would agree that the goals he lists—developing leadership skills, teaching and supervising of other coprofessionals, essentials of consultation work, long-term treatment of the severely dysfunctional, and geriatric psychiatry—represent important skills and knowledge areas in a residency program. However, we wonder if they must necessarily be learned in a community setting. We believe that a consultation-liaison setting in a medical center can provide ample opportunity for the resident to develop these skills (1). We would question whether administration, community consultation, and agency consultation are a required part of the core curriculum for first- and second-year residents. In our program, we provide a third-year track for residents interested in these special areas.

In summary, there are many paths to Mecca. It is our hope that each program will develop its own unique routes. We welcome letters like Dr. Solomon's in our continuing effort to modify and improve the educational objectives in our psychiatric residency program. His letter has helped us in this effort.

A Question of Significance

SIR: In their article "An Investigation of the Postpsychotic Depressive Syndrome" (January 1976 issue) Thomas H. McGlashan, M.D., and William T. Carpenter, Jr., M.D., found that "patients in the depressed group received psychoactive drugs more frequently." However, they reported that this relationship was not statistically significant ($\chi^2=3.35$, $p=.07$, Yates' correction applied).

Constructing the 2×2 table shown below (PPD=post-psychotic depressive syndrome) and using Fisher's exact test, I found p=.033, which meets the usual criterion of p<.05 for significance.

	Drugs	No Drugs
PPD	10	5
No PPD	4	11

MICHAEL FEINBERG, M.D., PH.D.
Ann Arbor, Mich.

Drs. McGlashan and Carpenter Reply

SIR: For chi-square with Yates' correction and Fisher's exact test, p=.033 by the one-tailed test. However, for the more conservative two-tailed estimate, p=.067. We rounded this figure to p=.07 and reported it in our article.

They Hear Music

SIR: Ross and associates (1) reported 5 cases of auditory hallucinations in nonpsychotic deaf patients. The patients' hallucinations consisted of continuous, vividly perceived music that reflected their musical memories. They were reluctant to discuss the problem lest people think them crazy.

I recently encountered a similar case in a 63-year-old man who had been beaten on the head 15 years previously. He is not deaf but has had tinnitus since the injury. He is in intensive psychotherapy with me for depression and is clearly not psychotic.

In April 1975 he began to hear entire songs in four-part harmony, and sometimes sings the tenor solo along with the songs. He finds the experience relaxing unless he dislikes the song, at which point he is able to change the music by singing aloud "amen." I might add that his favorites are Handel's "Messiah" and songs by Victor Herbert.

The "Ultimate Overstatement"?

SIR: In her editorial "Rape: 'The Ultimate Violation of the Self' " (April 1976 issue) Elaine Hilberman, M.D., appears to be carried away to such an extent that she detracts from the serious and scholarly tone and import of the papers in the topical section on rape and other forms of violence. For the sake of hyperbole, Dr. Hilberman chooses to bury in the fifth paragraph of her editorial the more accurate continuation of her title, namely, "Rape is 'the ultimate violation of the self' . . . *short of homicide*" (emphasis added). For thousands of years it has been men who have been sent off to wars to be killed and mutilated, men who have been the main victims of an unhappy assortment of homicidal activities, official and unofficial, and even men who have been the most "successful" suicides among the sexes. Just what is, we may ask, this "ultimate violation of the self"?

Again we find a surprising and gratuitous outburst of indignation when Dr. Hilberman states "It is not surprising that the four papers on rape in this issue were written by women." I have had no difficulty finding numerous articles and books by men on the subject that are empathic, significant, and helpful without ignoring or denigrating the unfortunate victims of forcible rape.

ROBERT L. GOLDSTEIN, M.D.
New York, N.Y.

Dr. Hilberman Replies

SIR: Having spent the last three years involved in rape-related projects, I am no longer surprised at the intensity of affect elicited by this issue. Dr. Goldstein is obviously angered by my position, with the main intent of his letter coming in the form of a character assassination. I find nothing substantive in his remarks, however, that would warrant a response.

ELAINE HILBERMAN, M.D.
Chapel Hill, N.C.

Pulling a White-Coated Tale

SIR: The excitement generated by Dr. Ronald J. Blank's letter about his inspiring experience with Sigmund Freud's tailor ("A White-Coated Tale," March 1976 issue) almost persuades one to overlook some temporal inconsistencies in the old tailor's account of his sartorial dealings with the father of psychoanalysis. While accepting this discovery as a valuable addition to the history of psychoanalysis, one must question the reported age of Dr. Blank's informant. The old man's vanity has led him to subtract a quarter of a century from his age, and in this vain peccadillo a larger fraud is revealed. Let me explain.

If one subjects Dr. Blank's report to the exegetical study such an important document deserves, one discovers that if the tailor was indeed in his "mid-eighties" when Dr. Blank encountered him, then, on the "fine day in the last part of the nineteenth century" when Freud entered his shop, the tailor must have been a precocious 5-year-old apprentice. Even more incredible was the outspoken lad's announcement to his distinguished customer when Freud came back to the shop a week later, "Well, Sigmund, I have known you for 10 years. . . ."

As I puzzled over this riddle, mourning the loss of the historical vistas opened by Dr. Blank's discovery but slammed shut by the hard facts of arithmetic, my dejected gaze fell upon a dog-eared copy of Grimms' *Märchen*.

In a flash, the solution to the conundrum revealed itself to me. The old tailor was none other than that protean gnome, Rumpelstilzchen. Still smarting from his defeat at the hands of that clever girl, and seeking revenge, he had fastened his hatred upon that famous student of myths and fairy tales, Sigmund Freud. It was at once obvious that the evil elf had diverted the distinguished scientist from his efforts to penetrate the mysteries of mythology by focusing attention upon

the trivia of the doctor's professional attire. No doubt he had hoped to wreck a noble career and, at the same time, to save the world of the Little People from the deflations of psychoanalysis. Failing in this malignant plan, the ageless incubus had fled the scene of his downfall, disguised as a tailor. On the heels of the psychoanalytic diaspora he had made his way to the New World, where he continued his campaign against the forces of enlightenment.

Happily, we can all breathe easier now that the threat has been removed. But for Dr. Blank's fortuitous visit, the impostor might have done serious damage to the scientific reputation upon which modern psychoanalysis rests. As we all know, however, exposure of these cases invariably destroys the evil spell and the danger evaporates. Once again, as any editor could have predicted, evil has been thwarted by timely publication of the facts. You are to be congratulated.

There is no need to thank me for my small addition to Dr. Blank's great discovery. The pleasure I have had in reporting it is reward enough.

DOUGLAS A. SARGENT, M.D.
Grosse Pointe Farms, Mich.

Dr. Blank Replies

SIR: In this day and age, the lot of an historian is never an easy one, particularly when his work is read by such a keen observer and exegetic as Dr. Sargent. I can still recall the words muttered by my mentor from the Department of History as he handed me my diploma on graduation day. As he shook my hand he looked me straight in the eye and intoned these words: "Thank God you are going into medicine!"

I must thank Dr. Sargent for pointing out the discrepancy in the tailor's age. After reading his quite plausible explanation for this discrepancy, I decided that I had but one choice if I were to regain my decidedly blemished image as an historian. I took the first plane to New York and rushed to the tailor's place of business.

There he was, sitting behind his sewing machine, singing happily to himself as he worked. He recognized me immediately and grasped my hand warmly. "So, Blank, how's the shrinking business in Ann Arbor?" he asked with a touch of sarcasm in his voice.

"Couldn't be better!" I responded. "However, there is a small matter that has arisen and so I have come to see you." I showed him the letter from Dr. Sargent, which he proceeded to read, chuckling to himself as he went.

"So, my friend, you are not much of a mathematician. Your clever friend has found me out. You psychiatrists are a clever lot. It is so—I lied to you. My real age is 105—I was born in 1871."

"But, why did you not tell me the truth—why have you embarrassed me so?" I asked.

"You—you are embarrassed because of a little white lie told by an old tailor. Shame on you! There are more important things in life than this."

"For instance?" I replied.

"For instance. For instance, he asks! Well, I'll tell you a for instance. What about my love life? What does a 70-year-old widow want with a 105-year-old man? There's no prospect in it. But a distinguished tailor in his mid-eighties—now this is another kettle of soup."

Just then the door opened and a very attractive elderly woman walked in, dressed in a mink coat and smelling like a fresh lilac. With a glint in his eye the tailor bounded up from his stool. "Anna, how nice to see you. Dr. Blank was just leaving. Come into the back—I have some hot tea and schnechen ready; also a new Wagner record I want you to hear." With that he took her by the arm and gently but firmly led her to the back room, having put a "closed" sign on his window. Before he disappeared he turned to me and said: "So, my friend. Do me a favor. Go back to Ann Arbor. There are more important things than to question an old man's age. You know, God created the earth in six days and on the seventh day he rested. As for me, I rested a little on the first and second days—so who the hell has time to rest on the last? Sei gesint!" And he was gone.

As I left the little shop, I could hear the gentle strains of a Wagnerian waltz amidst the rising crescendo of a woman's pleasant laughter.

Ann Arbor, Mich.

Correction

An error occurred in "Presidential Address: Psychiatry 1976—The Continuing Revolution," by Judd Marmor, M.D. (July 1976 issue). On page 742, at the beginning of the second full paragraph, the sentence "The emphasis in contemporary behavioral therapy is on growth and adaptation. . ." should have read "The emphasis in contemporary behavioral theory is on growth and adaptation. . . ."

The Mythic Image. Bollingen Series C, *by Joseph Campbell, assisted by M.J. Abadie. Princeton, N.J., Princeton University Press, 1975, 540 pp., $45.00.*

With *The Mythic Image* Joseph Campbell has crowned three decades of creative contribution to the study of culture and mythology. Perusing the written text, which is richly interwoven with quotations and reproductions of great art and arranged so that the eye can roam back and forth between the written word and its visual referent without flipping pages, is in itself a moving aesthetic experience. A critical review designed for psychiatrists is difficult because the point of view of *The Mythic Image* is broader than that of any single discipline and intentionally defies categorization.

The book is meaningful at many levels. Most evidently, Campbell demonstrates that the major civilizations of the world share a significant body of mythological motifs: the world dream and the world dreamer, the world mountain, the great mother, the miraculous child, the sacrifice, the resurrected hero, the serpent guide, the flower support, and many more, some of which involve complex spatial orientation and mathematical formulation. Through detailed analysis of these motifs throughout the world's time and space, Campbell makes a convincing case for their origin in the simultaneous resonance of the personal physical and fantastic experience, the immediate interpersonal environment, and the perceived mathematical order of earth (the seasons) and the celestial bodies (astronomy). His data suggest an origin of ideas in the early Bronze Age in the Near East and their transmission by diffusion throughout the rest of the world, including a hypothesized series of pre-Columbian transoceanic voyages.

The book cannot be subsumed within any single discipline because Campbell views mythology as a way in which man transcends objective categories. *The Mythic Image* jolts the reader into reconsideration of the Cartesian dualistic thinking that is characteristic of our "Western" minds. He confounds our belief in the distinction between subject and object and in the logic with which we assert that A is not not-A. He demonstrates the identity of the macrocosm and the microcosm in mythological relationships between some of our commonly accepted dualities, such as people and their perceived objects, the external and the internal, waking and dreaming, and life and death.

What is particularly impressive about *The Mythic Image* is that Campbell not only writes about his subject matter (poetry, art, history, science, philosophy, theology, religion, myth, and the questionable status of the dualistic distinction between subject and object), but he has also created a work that is identical with his subject, that is to say a piece of literature, art, philosophy, and theology. The reader will experience subjectively some of the very things Campbell writes about objectively.

The Mythic Image is of specific interest to psychiatrists. Students of object relations before the development of capacity for mature self-object differentiation (i.e., symbiotic, transitional object, and self-object relations) and students of early narcissistic development involving idealization and devaluation will find Campbell's descriptions of nondualistic thinking in various cultures and mythologies of great interest.

Campbell's description of Eastern religions, which assert that mythic figures are products of individual fantasy, is suggestive of relationships among psychiatry, psychoanalysis, and religion. The Buddhist Brihadaranyaka Upanishad asserts, "Whoever worships another divinity than his self, thinking, 'He is one, I am another' knows not." A Buddhist model of the mind, the Lotus stages in Tantric Yoga, postulates personal responsibility and psychic determinism, recognizes the existence of fantasy and projection, and hypothesizes a developmental hierarchy remarkably similar to Freud's psychosexual stages, in which successive preoccupations with anality and holding on, genital sexuality, and then power precede acquisition of sublimatory capacity and creativity. The goal of Yoga is to transcend the first three stages of living in a dualistic world.

The Mythic Image may stimulate the thoughtful reader to consider the future of Western culture and psychoanalysis. Our current interest in altered states of consciousness; mounting criticism of the glorification of sex, violence, and the dualism-based disciplines of science and technology; and heightened awareness of the problems of death and dying may reflect culture change. Should it become more personally important to achieve goals beyond sublimation, Eastern mythologies will have much to teach us personally and may also lead us as psychiatrists to reconsider our assumption that attainment of genital sexuality connotes normalcy and that states of self-object undifferentiation must be synonymous with infancy or psychosis.

MICHAEL D. ROBBINS, M.D.
Boston, Mass.

Psychopharmacogenetics, *edited by Basil E. Eleftheriou. New York, N.Y., Plenum Press, 1975, 468 pp., $28.00.*

Research in biological psychiatry has lately taken two paths: 1) the biochemistry of mental processes, closely linked to pharmacology, and 2) the genetics of psychiatric disorder, studied with a variety of new designs and techniques. The editor of this volume has brought together a group of papers that attempt to combine these two approaches in a new "double-hybrid science." Although this science is in its infancy, *Psychoparmacogenetics* emphasizes the fact that drug response—including drug abuse and drug idiosyncrasy—may vary with the genotype.

The difficulties of research in this area are not minimized. Fuller and Hansault discuss the role of background genes and the developmental environment, including the psychological burden on the individual of deviant reaction to drugs. Animal research has so far supplied much of the experimental data, and many of the chapters in the book are based on studies with mice.

Eleftheriou and his colleagues exploit an inbreeding technique (recombinant-inbred strains) that makes possible efficient genetic segregation and linkage analyses of loci responsible for particular drug responses. In these and other papers, variability in response to morphine, amphetamine, ethanol, and anesthetics is considered in relation to possible genetic determinants, although, as Oliverio and Castellano point out, the environment—including past experiences—can modify or abolish the effect of drugs.

An excellent and up-to-date review of genetics and alcohol consumption is provided by Eriksson, who covers such topics as twin, family, and adoption studies and the search for genetic markers. As with all clinical investigations involving genetics or pharmacology, the definition of the index population is one major difficulty. The other is the separation of genetic from environmental influences. Eriksson also describes the use of inbred rodent strains to study metabolic differences.

Another chapter of clinical interest is Omenn and Motulsky's review of clinical and experimental work on pharmacogenetics in man. The therapeutic and side effects of such drugs as succinylcholine, phenelzine, isoniazid, phenytoin sodium (Dilantin), nortriptyline, and the phenothiazines are related to gene-controlled pathways of metabolic excretion or activation. A survey of genetic findings in affective disorder is presented in the framework of the biogenic amine hypothesis, leading to the possibility (not yet achieved) of defining etiologically distinct types by means of drug response. The same hope is voiced in schizophrenia, although these authors feel that less progress has been made with schizophrenia than with the unipolar and bipolar affective disorders. Further discussions in this chapter relate to the hyperactivity syndrome, seizure disorders, and single-gene inherited diseases, such as the porphyrias, familial dysautonomia, the Lesch-Nyhan syndrome, and Huntington's disease.

The final chapter of the book, by Elias, describes multivariate statistical methods for the analyses of variance needed in this complex field.

In general this volume is well edited and up-to-date (the references are dated through 1975). There is some duplication and padding, and a few chapters dealing with drug side reactions have little to say about genetics. However, the book opens the window to an approach with important practical and theoretical implications.

Genetic differences in response to drugs will have to be considered more and more by the patient, by the clinician, and, as Kalow and LeBlanc emphasize, by society and the law. The field opened by this new approach should give the final blow to the nature-nurture dichotomy and the concept that genetic factors make for therapeutic nihilism. What clearer examples can there be of genetic-environmental interaction than those provided by psychopharmacogenetics?

JOHN D. RAINER, M.D.
New York, N.Y.

The Year Book of Psychiatry and Applied Mental Health 1976, *edited by Francis J. Braceland, M.D., Sc.D., Daniel X. Freedman, M.D., Arnold J. Friedhoff, M.D., Lawrence C. Kolb, M.D., Reginald S. Lourie, M.D., and John Romano, M.D. Chicago, Ill., Year Book Medical Publishers, 1976, 420 pp., $28.95.*

This annual publication reviews current psychiatric literature from mid-1974 to June 1975. The abstracts are grouped under the following headings: Neurophysiology, Biochemistry and Pharmacology, Psychology and Psychophysiology, Genetics, Learning and Memory, Mental Retardation, Child Psychiatry, General Clinical Topics, Clinical Psychiatry, Geriatrics, Psychosomatic Medicine, Psychotherapy, Psychoanalysis, Pharmacotherapy, Behavior Therapy, Psychiatric Nursing, Alcoholism, Drug Addiction, Drug Abuse, Suicide, Medicolegal, Community Psychiatry, and Social Psychiatry.

The editors, all of whom are well-known and experienced men in the field of psychiatry, have done a masterful job of selecting material that is important and pertinent. Their abstracts are clear and concise and reflect good editing without gimmicks. Their comments, which introduce most of the sections and follow some of the abstracts, are particularly good; one is left with a feeling of regret that there are not more of them throughout the book. The section titled Clinical Psychiatry is especially notable for such comments.

In his introduction to the book, Dr. Romano deals directly with a crucial issue when he writes that "the major function of Psychiatry, and one unique to it, is that it serves as a crucial bridge between genetics, biology and clinical medicine on one hand, and the behavioral sciences on the other." He emphasizes the need for psychiatry to "reaffirm our traditional and fundamental membership with medicine." These statements set the tone for a book that constantly reminds the reader of the medical orientation of psychiatry.

The busy psychiatrist who tries to keep pace with the ever-expanding literature will appreciate this book. He or she will be able to quickly review a large number of articles and then select those which he or she wishes to read at leisure in their original form. It provides a good way for those preparing for Board examinations or for the self-assessment test to survey current literature. In these days, when it is more important than ever for a physician to keep up in his field, a book like this is a welcome addition.

Washington, D.C.

Auditory Competence in Early Life: The Roots of Communicative Behavior, *by Rita B. Eisenberg, Sc.D. Baltimore, Md., University Park Press, 1976, 310 pp., $18.50.*

This is a difficult book to struggle through for someone who is not acquainted with the technology of audiometry and the instrumentation used in its practice and research. This technology ranges from the production of pure tones and the mere counting of the heart rate to the computer production of speech sounds and the interpretation of EEGs under various conditions of auditory stimulation. I found it worth the effort to follow the finely drawn scientific logic according to which many experiments have been organized into tentative schematics to interpret how sound becomes meaning.

Auditory Competence is essentially a report of the work of the Bioacoustic Laboratory of the Research Institute of St. Joseph's Hospital in Lancaster, Pa., from 1961 to the present. Dr. Eisenberg is the director of the laboratory. The research team included pediatricians, technicians, biochemists who shared their research populations with the laboratory, and, perhaps most important, an obviously cooperative and enthusiastic nursing service. The goal of the Bioacoustic Laboratory was to gain an understanding of the central nervous system mechanisms for dealing with sounds in such a way that, when all is well, sounds end up as a medium for

communication. The basic experimental mode by which this goal is approached is to study the development of the hearing and communicative functions in the growing infant. The work is far from complete, but this book provides an organized template on which findings are much more productively interpreted than has been the case in the past.

The book begins with the known neuroanatomy and physiology of the process of sound's transformation into meaning. Perhaps the most interesting simple finding is that sounds used in communication appear to be processed more by the right ear (left hemisphere), and other types of patterned sounds are integrated in the right hemisphere. This finding is dependent on the earlier finding that syllables ultimately to be used in communication are differentially effective in getting the infant to attend than are such pure tones, noises, and patterned sounds as music.

In the last decade or two, psychiatrists have become used to thinking about the biochemical substrates of normal and abnormal human behavior, but there has perhaps been a decline in attention to the sensory mechanisms that furnish the stimuli to set off the biochemical substrate. This book suggests the detail that psychiatrists must somehow incorporate into their psychodynamics as they attempt to find the significant input factors and situations that indicate what meaning will be placed on sounds by the higher integrative centers in the brain.

This book is a helpful reminder of the complexity that underlies the simplest of psychodynamic formulations.

PAUL V. LEMKAU, M.D.
Baltimore, Md.

To Each His Farthest Star: University of Rochester Medical Center 1925–1975, *edited by the University of Rochester Medical Center Publications and Publicity Committee. Rochester, N.Y., University of Rochester Medical Center, 1975, 539 pp., no price listed (paper).*

This interesting volume commemorates the 50th anniversary of the University of Rochester Medical Center. It consists of a series of 32 essays by such officials as university presidents and faculty members of the institution and an appendix by John Romano, Distinguished Professor of Psychiatry. Robert S. Morrison, an outstanding physician and former foundation executive, writes an "Outside View." The publications committee worked for a period of 2 years to put together a comprehensive and fascinating story of the birth and growth of a medical school. The essays presented give a selective history of the major developments in the school's history; in so doing they provide a running account of the major issues that beset medical education in this country during that half century.

The book is dedicated to George Hoyt Whipple, Nobel laureate and dean of the school from 1921 to 1953. This tenure is of itself remarkable as one thinks of the very short halflife of medical school deans today. Wallace O. Fenn, Distinguished Professor of Physiology and himself a bit of a legend, made the address when an auditorium was dedicated to Dr. Whipple in 1950; the book begins with a record of that address.

The early years of the medical school are introduced by Dr. Atwater, Professor of Medicine. His fetching title is "A Modest But Good Institution . . . and Besides There Is Mr. Eastman." In reading this work one gets the feeling of the warmth of an official family with a wonderful dean and a capable, dedicated faculty, all of whom are proud of their school.

The essays maintain a high level throughout the volume, ending with John Romano's delightful description of the hunt for an essential recording under the title, "Everything *Is* Up-to-Date in Kansas City." Naturally, the book will have most interest for those who have had any connection with the University of Rochester, but it does, as the publications committee hoped, "provide a window through which one may look out upon the broader scene of medical education, research, and clinical service in the nation at large."

F.J.B.

Involuntary Treatment of the Mentally Ill: The Problem of Autonomy, *by Michael Alfred Peszke, M.D. Springfield, Ill., Charles C Thomas, 1975, 146 pp., $10.75.*

This brief monograph deals with legal and psychiatric implications of involuntary commitment and involuntary treatment of the mentally ill. Dr. Peszke takes his stand on the medical model, which is everywhere under attack and is rapidly being rejected in the courts and repudiated in the legislatures of the United States.

Dr. Peszke excised the intellectual heart of this monograph and presented it in this journal (1). Having commented on that article (2), I looked forward to this monograph, but I found it somewhat disappointing. Peszke comes through in this text as a first-rate clinician with a good mind and a genuine understanding of the legal issues. There are real insights everywhere, but he could have used good editing. For example, he is uncertain about his audience and therefore does not provide enough basic psychiatry to orient the naïve lawyer or enough basic law to orient the naïve psychiatrist. Important ideas are tossed off without being explored and developed, e.g., the practical limitations of the due process model and the standard of dangerousness.

In developing his own position Dr. Peszke rejects the radical critics of psychiatry without confronting their arguments about the ontological status of mental illness. He also fails to confront the more prosaic problems of diagnostic reliability and validity.

Not having met these criticisms head on, he is forced to rely on argument by analogy; e.g., because we would treat an unconscious patient with a subdural hematoma we should treat the mentally ill patient with an acute schizophrenic disturbance. Arguing by analogy in this way begs all of the tough questions.

Peszke perceptively recognizes that, however weak its foundation, the central premise of any medical model must be the idea that the mentally ill are incompetent to act in their own interest. As he inelegantly puts it, "Mental illness coerces the free will." Thus Peszke places at the center of the medical model the presumption of the lack of free will. In contrast, the entire thrust of recent legal developments is to presume competence and to give the mentally ill their rights whether they are able to exercise them or not.

I think I can take Peszke's side in this argument, but I wish he had made it clearer which mental illnesses "coerce the free will."

For the reasons already stated, I cannot recommend this book to the average clinician. However, Dr. Peszke demonstrates a level of understanding of the issues that will delight those who are familiar with the field. The discipline of forensic psychiatry faces a knowledge explosion; it requires a

growing cohort of scholars who understand both the psychiatric and the legal issues. The author of *Involuntary Treatment of the Mentally Ill* can be counted in that small group.

The Nuremberg Mind: The Psychology of the Nazi Leaders, *by Florence R. Miale and Michael Selzer. New York, N.Y., Quadrangle/New York Times Book Co., 1976, 302 pp., $10.95.*

Since Freud's pioneering study of Leonardo da Vinci, the application of psychoanalytic theory to the study of historical figures has gained increased interest and respectability in the scientific marketplace. The psychohistorian, like the psychoanalyst and the archaeologist, has to tease out conclusions and reconstructions from bits and pieces of surviving material. In few instances have these bits and pieces of surviving material included psychological test data on the figure under study. *The Nuremberg Mind* is a noteworthy exception because its two authors (one a widely respected Rorschach interpreter and the other a political scientist) lead us on a journey through the maze of Rorschach records (with interpretations) of 16 of the major Nazi war criminals who were tried in Nuremberg in 1945 and 1946.

The introduction, an interesting account in its own right, is provided by the psychologist who administered the 16 Rorschachs while he was assigned to the prison staff at Nuremberg. Beyond setting the stage for the research, his account allows the reader to evaluate the context within which each Rorschach response was delivered, including the nature of the patient-examiner relationship.

The meat of the book is, of course, the individual protocols and the authors' interpretations of them. This part of the book may be evaluated in terms of both substance and methodology. With respect to the former the material is fascinating. One is furnished a wealth of little-known raw clinical material as well as the opportunity to gaze over the shoulder of a gifted clinician as she skillfully moves from observation through inference to conclusion. Readers are invited either to compare their own responses to the blots with those of the war criminals or to pit their interpretations against those suggested by the author.

As to methodology, the book is not without shortcomings. Despite advance warnings, I found the test interpretations at times judgmental and at other times dictated by information beyond that which could readily be gleaned from the actual test responses. The acts of these war criminals are legendary. More than 30 years after World War II, they, together with the atrocities they perpetrated, still revive the deepest, the most primitive, and the most intense feelings in many of us. It is therefore difficult to imagine how a study such as this can be conducted without counterreactions and countertransference reactions playing a decided role.

Beyond limitations in methodology, this study of the personality structure of 16 Nazi leaders, using information obtained from Rorschach protocols, has a great deal to contribute to our understanding of such varied and important areas as primitive aggression, narcissism, object relations, superego development, and self-representation.

Toronto, Ont., Canada

Perversion: The Erotic Form of Hatred, *by Robert J. Stoller, M.D. New York, N.Y., Pantheon Books (Random House), 1975, 231 pp., $10.00.*

In this interesting book Stoller advances several ideas, chief among which is a psychodynamic theoretical position on the etiology of the "perversions," a term he dislikes but feels has some utility in labeling the sexual pathologies that have fantasied hostility at their core. The hostility may be self-evident (as in sadistic behavior) or covert and benign (as in peeping).

Stoller introduces his theory by pointing out that in the past decade or two research on aberrant sexual behavior has not focused on clinical psychodynamic investigation. Instead, it has seemed to accent that such behavior may be found in other species, is ubiquitous in man, and at times seems to be the product of brain and hormonal factors that can function independently of anything called psyche. The findings of these researchers make them "regret society's moral stance that sexual aberration is unnatural—sinful—and the repressive action that follows" (p. ix).

Stoller rolls up his sleeves and in his honest fashion wades into the psychological factors that he has found in the analysis of "perverted" patients. He is careful to label his formulation as theory and presents it as a position that others may examine and tear apart or modify. He strongly advocates that clinical investigation not be forgotten as a research tool.

Stoller separates out those sexual aberrations produced primarily as a lifelong attempt to "cure" psychic stress from those in which that dynamic is not at the root of the behavior. He says,

> I believe that perversion, but not all aberration, is a product of anxiety and that perverse sexual behavior has sprinkled through it remnants, ruins, and other indicators of the past history of one's libidinal development. . . . If the observer knew *everything* that had happened in the life of the person he is studying, he would find these historical events represented in the details of the manifest sexual act. The observer would then know when and why this person gave up what he would have most liked erotically, to choose the alternatives that are the perversion's scenario. . . . The perversion is a *fantasy* put into action—a defensive structure raised gradually over the years in order to preserve erotic pleasure. The desire to preserve that gratification comes from two main sources: (1) extreme physical pleasure. . . ; (2) a need to maintain [gender] identity. (p. xiv)

The author uses numerous case reports to illustrate the points he makes and carries the reader along in a convincing fashion to see how he arrived at his conclusions.

In the concluding section, titled Social Issues, Stoller examines several matters of current psychiatric interest. In the chapter "Is Homosexuality a Diagnosis?" he states that it is not and that it should be scrapped, not because of social pres-

sure to do so but because it represents a hodgepodge of differing etiologies and cannot function as a true diagnosis that has value for scientific understanding. He feels the same way about most of the other "diagnoses" of psychiatry.

In the chapter "Sex as Sin," Stoller observes that sexual "sinning" is a popular pastime in our society, wonders why, and finds the answers in intrapsychic dynamics. His first clue was the long-known fact that an awareness that one is sinning often markedly increases sexual excitement. On analysis he finds a correlate with the perversions, i.e., a sense, however dim, of a fantasied wish to hurt. As a strategy of social action, he suggests that those who wish to increase sexual freedom ought not lean too heavily on the argument that the sense of sin exists only as an effect of one's enslavement by repressive historical processes: "The sense of sin may not disappear simply because we announce that it is outdated, and the complex richness of human sexual excitement will be missed if we exclude sin from our studies" (p. 209).

The final chapter, "The Necessity of Perversion," is a wrap-up of the ideas he has put forward, namely, that these pathologies may be viewed as defenses against intrapsychic conflicts to preserve the gender identity of the bearer.

This book gave me a new frame of reference for looking at some of the perversions. I recommend its reading. It is written in an interesting, nontechnical manner that is almost conversational and therefore easy to follow. Jurists and clergymen would find, I believe, that it would furnish a larger lens for looking at some of the knotty problems they, as well as psychiatrists, face.

Death Inside Out: The Hastings Center Report, *edited by Peter Steinfels and Robert M. Veatch. New York, N.Y., Harper & Row, 1975, 149 pp., $7.95; $3.50 (paper).*

Death has somehow lost the naturalness it was once accorded by physicians, families, and even dying persons themselves. Perhaps an illusion of environmental mastery stemming from scientific and technical advances has created an atmosphere in which the event has seemed an adventitious product of disease. As though immortal, dying men and their attendants have looked upon death not only as an unwelcome but as an unnecessary imposition. Whatever its origin, this attitude has made of death an event to be denied and opposed at all costs rather than one to be accepted as a natural ingredient in life and a potent force in shaping individual existence. It has made death the doctor's enemy and encouraged physicians to treat fatal illness as though it were curable disease. The result has been demeaning to the dying individual, the physician, and the community.

This attitude is commented on by the authors of *Death Inside Out*, a collection of essays from the Hastings Institute of Society, Ethics, and the Life Sciences. The authors offer penetrating analyses of current death-related beliefs and practices. Paul Ramsey, for example, expresses frustration with campaigns to naturalize, romanticize, or dignify death. For him, "death with dignity" has become a meaningless slogan serving only to impose its thoughtless dictates on the dying. He also reminds his readers that, although death may be a source of man's nobility, it is also a source of defeat and despair, an affront to the prideful mortal.

In a similar vein Leon Kass notes that dignity is, after all, a quality that only the dying person can supply; still, he urges those caring for the dying to avoid contemptuous treatment. Robert Morison, on the basis of his view that life and death are part of a continuum, believes that attempts to define death are scientifically and philosophically unsound and should be abandoned. Instead, he tells us that difficult decisions regarding the length of life must be guided by complex cost-benefit analyses. Dr. Kass counters that he sees no need to abandon the concept of death as a transitional state. He emphasizes that the physician's primary concern is always the welfare of his or her dying patient and believes that the interests of family and community should not be allowed to divert his or her attention. And so goes the discussion.

Essays from many disciplines—medicine, ethics, religion, and history, for example— are brought together in this volume in a spirit of thoughtful inquiry and debate. They are scholarly and stimulating. As with other collections of this kind, however, the book lacks a unifying theme and makes no attempt to deal with its subject systematically. Fostered in an atmosphere of continuing intellectual exploration, it lacks the practical grounding that would give it appeal for most physicians. Nevertheless, those with professional interest in death and dying will find the book rewarding reading.

RUSSELL NOYES, M.D.
Iowa City, Iowa

The Human Context: Environmental Determinants of Behavior, *by Rudolf H. Moos. New York, N.Y., Wiley-Interscience (John Wiley & Sons), 1976, 437 pp., $18.95.*

"Whence come those mysterious influences which change our happiness into discouragement, and our self-confidence into diffidence? One might almost say that the air, the invisible air, is full of unknowable Forces, whose mysterious presence we have to endure."

This question, posed by Guy de Maupassant in his story "The Horla," has been answered admirably by Professor Moos in *The Human Context*. As psychiatrists we have as our chief interest the individual; we take a history, consider early formative influences, and place our patient on the dissecting table of the couch. Rarely, however, do we achieve the larger view and fully comprehend the human person in dynamic and ever-changing equilibrium with his environment. Moos has written an elegant and comprehensive account of the relationship between human behavior and the real world in which we live.

In the first part of his four-part book, Moos discusses the following trends in human-environmental relationships:

1. The broad historical and geographical perspective that attempts to explain the decline and fall of entire civilizations and whose most prominent exponent was Arnold Toynbee.
2. The growth of human and cultural ecology, including the epidemiology of mental illness and air and noise pollution, which has become particularly timely with the advent of the supersonic airplane.
3. Environmental determinants of health and disease, with attention to the natural and social climate in which people live.
4. The rise of organizations and bureaucracies. (Here, Moos refers to his own work demonstrating the effect of social climate in influencing the turnover rates of psychiatric wards.)
5. The relationship of experimental psychology and personality theory to social learning theories, conditioning, and social climate.

6. Architecture and environmental psychology.
7. The ecology movement, the sudden realization that planetary resources are finite, the conservation movement, and the "politics of less."

Professor Moos then states his own position, the social ecological approach, according to which he attempts (and succeeds in this, in my opinion) to synthesize our physical and social environments and their impact on the individual. At the same time the social ecological approach emphasizes individual adaptation, adjustment, and coping with an environment that may be stressful, limiting, selective, releasing, or challenging. In Moos's words, "We conceive of social ecology as the multidisciplinary study of the impacts of physical and social environments on human beings." Social ecology is humanistic and is dedicated to enhancing the quality of human environments, thus improving the quality of human life.

At the end of his extended introduction, after delicately skirting the question of free will, Moos goes on in the second and third parts of this book to consider in rich detail the physical and social environments. It would be difficult to select examples of Moos's style from the wealth of material cited. One idea that appealed to me is that just as doctors and dentists see their patients periodically for checkups, architects and designers should reexamine their creations to see if they are healthy. If they are diseased, like the Pruitt-Igoe housing project in St. Louis, Mo., for instance, one assumes that radical surgery in the form of the wrecker's ball should be applied.

In the fourth part of *The Human Context*, Moos discusses three selected Utopian environments: Thomas More's Utopia, B.F. Skinner's Walden II, and the experimental Oneida community of 1848–1880 in New York State. Moos is critical of all three Utopias, pointing out that they display only superficial understanding of man's relationship to the environment. Finally, Moos tentatively makes conclusions regarding human environments, including the effects of weather upon performance, physical space and building design in relation to behavior, and social climate and its effects on personality development. Moos argues persuasively for innovative procedures for helping people adjust to new environments. He feels that not enough attention has been paid to the milieu and its effects on the individual personality.

It is impossible in this brief review to do full justice to the vast landscape surveyed in this book. The work ends on an optimistic note, declaring that "our best hope for the future may be in a fusion of the visionary goals of utopian thinkers with the practical policies espoused by environmental advocates." This is an entirely appropriate conclusion in our bicentennial year to a book that deserves a place in every psychiatrist's library to contrast with and to complement everything written about individual psychology.

FRED B. CHARATAN, M.D.
New Hyde Park, N.Y.

Marijuana and Health Hazards: Methodological Issues in Current Research, *edited by Jared R. Tinklenberg. New York, N.Y., Academic Press (Harcourt Brace Jovanovich), 1975, 171 pp., $8.50.*

This volume contains 14 papers and 5 discussions from a recent conference on current concepts of effects of marijuana on human beings. Particular reference is made to marijuana's influence on genetics, immunity, testosterone, and the central nervous system as well as its role in the development of psychiatric problems. Representatives of most of the controversial findings or points of view are included. Indeed, the list of authors reads like a *Who's Who in Marijuana Research*, if there were such a volume.

The general point of view expressed is that marijuana is by no means harmless but that its effects are far less destructive than most drugs in common use (alcohol, heroin, cocaine, or, possibly, tobacco). Most of the firmly held differing opinions are clearly expressed, and even the confusion is well organized. For anyone wishing a succinct survey of the current state of informed opinion regarding the effects of marijuana on human beings, this volume is strongly recommended.

DANA L. FARNSWORTH, M.D.
Boston, Mass.

The Psychology of Adolescence: Essential Readings, *edited by Aaron H. Esman. New York, N.Y., International Universities Press, 1975, 550 pp., $20.00.*

In this volume Aaron Esman brings the reader a treasure trove of material on the developmental aspects of adolescence, thus saving us many dollars and much footwork that would otherwise have been spent searching out the classic works presented here.

After giving Margaret Mead and a few others space to sketch in some cultural determinants, Esman provides the theoretical constructs of Sigmund and Anna Freud, Erik Erikson, Jean Piaget, Peter Blos, and Daniel Offer, each of whom discusses his or her point of view in his or her own distinctive style. Esman wisely introduces each chapter with only a few sentences designed to whet the appetite for what follows rather than interpreting or condensing the subject matter.

The third section of the volume covers psychopathology in a comprehensive manner, including alienation, role diffusion, homosexuality, and drug abuse—problems that some might consider normative crises rather than pathology per se. The articles chosen for inclusion here are less consistently excellent than those in the preceding section. The narrowness of focus and comparative shallowness of the treatment of drug use and psychosis are compensated for by the fine delineations of adolescent turmoil by James Masterson and of delinquency by August Aichhorn.

The fourth section of the book deals primarily with the influence of contemporary society on adolescent development and contains some outstanding contributions to the concept of superego development. In their article on the permissive society and the superego, Henry and Yela Lowenfeld note that today, "the decisive repressions concern not the id but the superego." They go on to show how the contemporary father who acts more like a weak older brother does not lead the child into a milder superego development but into an increase of fantasy and projections that magnify the power and cruelty of the parents.

Another exciting chapter in this section is E. James Anthony's on parents' and therapists' reactions to adolescents. He writes convincingly of the ways young people stimulate unconscious feelings of envy and longing in the adults with whom they interrelate—sometimes to the point of reactivating an adolescent crisis in a parent.

This is a book that, as its subtitle states, is indeed essential reading for the uninitiated. For the experienced clinician it provides a pleasant refreshment and, in its entirety, a source

of new ideas to be intrigued by for quite a space of time. This will make an excellent textbook.

GRAHAM B. BLAINE, JR., M.D.
Cambridge, Mass.

Alcohol in Colonial Africa. Finnish Foundation for Alcohol Studies, Vol. 22, *by Lynn Pan. Helsinki, Finland, Finnish Foundation for Alcohol Studies (New Brunswick, N.J., Rutgers Center of Alcohol Studies, distributor), 1975, 121 pp., $5.50.*

Drinking Habits Among Alcoholics. Finnish Foundation for Alcohol Studies, Vol. 21, *by Salme Ahlström-Laakso. Helsinki, Finland, Finnish Foundation for Alcohol Studies (New Brunswick, N.J., Rutgers Center of Alcohol Studies, distributor), 1975, 216 pp., $8.00.*

Alcohol in Colonial Africa is a monograph of general interest to all who are concerned about the history of alcohol use and abuse. Although there had been an African industry involving such beverages as pahn wine before the colonials came into power, the colonials produced a major new social problem in that alcohol became the payment for slaves. An early nineteenth-century African chief put it succinctly: "We want three things, powder, ball, and brandy, and we have three things to sell, men, women, and children." Thus the two great evils of colonial Africa—the slave trade and liquor traffic—became close partners.

Alcohol also became a major source of income through duties for the colonies. As taxes and duties rose, the quality of the alcohol dropped but not the volume. "Trade gin" was considered barely consumable for the colonists, who were assured a supply of good liquor from home. In fact, this supply was considered indispensable if civil servants were to be kept in the colonies; their rates of alcoholism were very high.

A series of international conferences on alcohol control was largely ineffective because commercial factors were stronger than moral factors at these conferences. In all, Pan describes a rather unpleasant picture of man's greed and lack of concern for his brothers of another color.

Drinking Habits Among Alcoholics is a study of drinking habits before and after a revision in alcohol beverage legislation that took effect in Finland on January 1, 1969. A comparison is made of drinking habits in Helsinki and in two small rural communities in 1968 and 1969.

The studies show a sizable difference in absolute alcohol consumption among alcoholic men in different locales—24.5 l a year in Helsinki, 12.5 l in one small town, 6.0 l in the other, and 3.6 l for all of the men studied. The major difference between alcoholic and nonalcoholic men was not in frequency of drinking but in occasional large consumption.

The legislative change made "medium beer" (4.5%) more readily available by increasing the number of retail outlets from 132 to 17,460. This resulted in a 4-fold increase in medium beer consumption in Helsinki and a 12- and 28-fold increase in the two rural communities. Overall alcohol consumption went up 46%. Medium beer increased as a proportion of alcohol consumed, although less so for alcoholic men; use of nonbeverage alcohol declined; fewer people were abstinent; and alcoholic men in Helsinki had more days of drunkenness, although, surprisingly, fewer days of drunkenness occurred in the rural settings.

This study was of considerable interest in Finland because of the controversy between liberal and hardline attitudes toward controlling alcohol use and abuse. It would be of similar interest to us in the United States, but this book is not recommended for casual reading or for general education about alcoholism.

ROBERT A. MOORE, M.D.
San Diego, Calif.

Psychiatry and Mysticism, *edited by Stanley R. Dean, M.D. Chicago, Ill., Nelson-Hall, 1975, 398 pp., $15.00.*

This book is a compilation of papers presented at three symposia on metapsychiatry organized by Dr. Dean for APA, plus a few invited papers. Metapsychiatry is defined as "the base of a pyramid whose other sides are psychiatry, parapsychology, philosophy and mysticism" (p. 5). Obviously, this covers a lot of territory, a fact reflected by the book's contents—26 papers on a great variety of topics. Some are very general, some are reviews of specific areas, and some are detailed reports of experiments or experiences. The book is loosely organized into four sections. The first is a miscellany consisting primarily of general discussions; the second includes papers on energy fields and meditation; the third reports on work on psychic healing; and the fourth reports on experiences "involving an expansion or extension of consciousness beyond the usual ego boundaries and the limitations of time and space" (p. 314).

Some of the experiences recorded here would strain even the credulity of the White Queen in *Alice Through the Looking Glass*, who boasted that she could believe as many as six impossible things before breakfast. For example, some subjects under LSD are reported to have had "illuminating insights as to what it feels like when a snake is hungry [or] when a turtle is sexually excited" (p. 328). One wonders how the author knew whether the insights were illuminating or delusional.

The reader must frequently shift intellectual gears, as it were, in order to cope with the book's inclusion of phenomena that can be explained within the conceptual frame of Western thought and phenomena that cannot. The first group includes biofeedback, the relaxation response, Kirlian photography (which may simply be a means of detecting changes in sweating), and healing by laying on of hands. These phenomena do not violate Western concepts of time, space, or causality. Discoveries of hitherto undetected forms of energy or patterns of organization of the nervous system present no greater conceptual problems than the discovery of radio waves, bioluminescence, or the circulation of blood.

The other class of phenomena, for which there is no agreed-on encompassing term, can be explained only by the assumption that they occur in a different kind of reality in which events do not follow the conventional laws of time, space, and causality. This reality, which, incidentally, is remarkably similar to that of subatomic physics, is the seat of ESP, mental telepathy, clairvoyance, precognition, and transpersonal experiences. As Silverman points out in his excellent paper, such experiences cannot be studied by the usual methods of experimental psychology because the analytic mental set required by these techniques blocks the experiences. However, they can be approached indirectly by statistical methods that take into account their fluctuating and inconstant nature and by modern neurophysiological techniques that detect changes in stimulus sensitivity while persons are in these states of consciousness.

Despite the growing body of evidence for the existence of

transpersonal experiences, much of which is as rigorous as that for any phenomena accepted as valid, these experiences continue to be rejected by the majority of scientists. This attitude rests in part on the justifiable fear that to accept them would open the floodgates to superstition and error. Indeed, the field of parapsychology is a happy hunting ground for charlatans who prey on the self-deluded. The vehemence of the reaction of many scientists, however, is uncomfortably similar to that of true believers in any cosmology toward a rival world view.

Most of the contributors to this volume are well-known authorities; the chapters are clearly written and free of exhortation. Scholarly needs are met by adequate bibliographies and an index. Psychiatrists who are curious and brave enough to want to venture into the still largely uncharted seas of metapsychiatry will find this book to be a good guide.

JEROME D. FRANK, M.D.
Baltimore, Md.

Cathexis Reader: Transactional Analysis Treatment of Psychosis, *by Jacqui Lee Schiff. New York, N.Y., Harper & Row, 1975, 193 pp., $9.95.*

This valuable book describes ways of understanding interpersonal transactions with difficult patients and establishing a problem-solving alliance. It defines ideas and behaviors, including those from transactional analysis, operationally. Given that healthy individuals are aware of themselves and their environment, spontaneous in responding, and capable of intimacy, what do people who appear unaware, unresponsive, and withdrawn do with their energy (cathecting)?

The answer given by Schiff and collaborators is that these people use passive behaviors, i.e.: 1) doing nothing, 2) overadapting (conforming to external demands like an automaton), 3) agitation (such body or verbal activity unrelated to problem solving as smoking, pacing, and circular talking), and 4) violence or incapacitation (violence and incapacitation are together because both follow increasing agitation).

To maintain passive behavior these patients use discounting, grandiosity, and thought disorders, i.e., overgeneralizing, overdetailing, and escalation. The passive behavior is intended to establish a symbiosis in which two or more people behave as if they form one whole personality containing the three major ego states of Parent, Adult, and Child.

The developmental scheme elaborated in *Cathexis Reader* includes the child's developmental needs and activities and the complementary symbiotic activities of the parents for each stage. If the parents do not provide the phase-appropriate responses or if they attempt to prevent the normal disruption of each symbiosis by growth, pathology may result. This is understood as an attempt to get needs met by attempting to reestablish the symbiosis at the point where the frustration occurred or to reestablish the symbiosis that was successful before the frustration occurred.

For instance, the agitated patient paces, saying, "Doctor, can't you do something?" If the doctor enters this symbiosis, he or she becomes the Parent who nurtures and the Adult who figures out what to do. The patient becomes the Child who feels bad and needy. This discounts the ability of the patient to cathect his or her own Parent and Adult as well as the feelings and needs of the doctor.

The therapist chooses the ego state he or she believes will be effective, deciding whether entering the symbiosis is desirable. The Parent says, "You sure sound upset. Slow down. Take it easy." Instructions are then given forcefully. The patient then overadapts and can think better than he or she could while agitated. The statement "Tell me what the problem is" will now elicit Adult information from the patient, demonstrating to him or her that problem solving involves thinking and that it is grandiose to believe that pacing up and down really changes anything or that escalation to violence will help.

If unable to stop the escalation of agitation into violence, the therapist and other members of the group provide safe physical controls until the storm has passed. After this the patient is able to express his or her needs more clearly and to work with others. The therapist does not discount the agitation. He or she proceeds through the following: 1) "You sound upset" (stimulus), 2) (implicit in statement 1) "That matters to me" (significance), 3) "That means you have a problem" (problem to be solved), and 4) "You can tell us what the problem is" (ability to solve problem).

Cathexis Reader develops the discount idea in detail, and this is very valuable. Disturbed patients and the people who work with them often discount what is happening, its solvability, and the capacity of patient or therapist to take effective action.

Because of space limitations, I will not discuss the many other useful ideas in this book. I have only one caveat: the subtitle is misleading. This book is only an introduction to, not a description of, the treatment of psychosis by transactional analysis. I hope that book will soon be written by Schiff and collaborators.

ROBERT C. DRYE, M.D.
Watsonville, Calif.

Community Mental Health Legislation: The Formative Process, *by Henry A. Foley. Lexington, Mass., Lexington Books (D.C. Heath and Co.), 1975, 148 pp., $14.00.*

Like the author of this book, I worked at NIMH; I watched many of the processes that he reports on in this book. He reconstructs a history in which I participated.

In the foreword Samuel Beer suggests,

> Dr. Foley shows how federal officials identified an important problem, promoted the research necessary for a solution, attracted a coalition united in its goals and successful in its lobbying, and, finally, administered the resulting program in a manner faithful to the letter and the spirit of the legislation, and to the intent of the office. In short, his unconventional thesis is that the federal government is capable of action that is rational, purposive, and non-incremental.

Reviewing this book and reviewing my own experience, I believe that the logic of this development was indeed present. One can see this beautiful straight line of rational processes retrospectively. As a psychiatrist deeply concerned with social change, however, I am not sure whether I can believe everything that is rationally presented.

In reading *The Double Helix* by James Watson (1), I was awed by the fact that the discovery of the DNA molecule was less a straight, rational process and more one that we might call human. In the development of community mental health legislation as well, the waves and crises, cycles, annoyances, angers, perceptions, and misperceptions were

part of the process. People floated in and out of the project. Indeed, as the size and scope of the program became larger and involved more money, it began to attract more and more people who, for a variety of reasons, played critical and important roles in modifying and affecting the policy implementation.

Perhaps my own view is skewed by the glasses I wear: it is my strong belief that mental health is an area of concern and responsibility of more people than those included in the mental health professions. Mental health should therefore be firmly implanted within the value systems of other programs—education, labor, the Department of Defense, the Children's Bureau, Social Security, and a host of others. What actually happened was that as the mobilization for community mental health developed, a set of pressures that would guarantee a potential lack of success was also mobilized.

It is my belief that the side effects of the legislation probably had a bigger impact than the direct activities of the community mental health center. I am not too sanguine about the output or results of the program. I *am* sanguine and excited about the fact that the spinoffs have led to a tremendous change in the way we view psychological problem areas. Indirectly, its failure led to the establishment of many new ways of approaching psychological problems. It also led, in some instances, to a reintegration of psychiatry and mental health with medicine itself.

What then do we have in this book? If one believes that the people who, as Samuel Beers says, developed a rational resolution to a problem were right, we have an illustration of how political power can be mobilized in such a way that the appearance of dealing with a mental health program is achieved. However, if one believes, as many within psychiatry and the other mental health professions do, that there are alternative ways to deal with some of the issues involved, we have here a relatively narrow-minded implementation of an idea of what the issues were in psychiatry and mental health.

I would like to say, personally, that before the outset of community mental health activities in high-budget form, NIMH served under Robert Felix as a leader in understanding issues that were truly concerns of psychiatry, human development, psychosomatics, and many of the behavioral sciences. Its activity spun off many ideas that were later implemented by a variety of programs throughout and outside government. One thing not documented by Foley is that the orientation of NIMH as facilitator, stimulant, guide, and leader was replaced by an orientation according to which, in my opinion, NIMH became a closed organization concerned with selling a particular kind of product, i.e., community mental health.

It is only more recently, as the budgets are being cut and the available resources are less plentiful, that questions are again being raised about the allocation of mental health funds.

I think Henry Foley should be complimented on a fine documentation. I agree with him that some of the other political science conceptual models concerning how programs develop and change are not clear pictures of the process. If, however, this were more than a report, if it carefully evaluated whether we have done something about the mental health of the population of the United States, I would say that we did so only indirectly, and that much of the energy that went into community mental health legislation did not lead to an outcome that truly changed the lives of the people who are mentally ill.

Sadly or fortunately, the real heroes are not the legislators or the policy makers, but the people who have dealt with people in trouble daily: psychiatrists, psychologists, aides, neighbors, bartenders, and all those caretakers of society—official and otherwise—who have expended their human social energy in helping to heal the mentally ill. There are vast numbers of these people who need to be recognized and acclaimed because it is they who in the last 25 years have done the important job.

ROBERT C. DRYE, M.D., is Staff Psychiatrist, Western Institute for Group and Family Therapy, Watsonville, Calif.

LEONARD J. DUHL, M.D., is Professor of Urban Social Policy and Public Health, University of California, Berkeley, College of Environmental Design and School of Public Health, Berkeley, Calif., and Clinical Professor of Psychiatry, University of California, San Francisco, School of Medicine, San Francisco, Calif.

Books Received

This listing acknowledges the receipt of recent books. Books of particular interest to the readers of this journal will be reviewed as space permits, and copies of the reviews will be sent to the publishers. Books cannot be returned to the publishers.

Creativity: The Magic Synthesis, *by Silvano Arieti. New York, N.Y., Basic Books, 1976, 429 pp., $15.95.*

Aminergic Hypotheses of Behavior: Reality or Cliché? National Institute on Drug Abuse Research Monograph 3, *edited by Bruce Kenneth Bernard, Ph.D. Rockville, Md., NIDA, 1975, 148 pp., $6.75 (paper).*

Police Social Work, *by Edward M. Colbach, M.D., and Charles D. Fosterling, M.S.W., M.P.H. Springfield, Ill., Charles C Thomas, 1976, 155 pp., no price listed.*

Group Relations Reader, *edited by Arthur D. Colman and W. Harold Bexton. Sausalito, Calif, GREX (Minneapolis, Minn., A.K. Rice Institute, distributor), 1975, 370 pp., $10.50.*

ESP Party Games, *by Richard De A'Morelli. Chatsworth, Calif., Major Books, 1976, 160 pp., $1.25 (paper).*

Emotional Expression in Infancy: A Biobehavioral Study. Psychological Issues Monograph 37, *by Robert N. Emde, Theodore J. Gaensbauer, and Robert J. Harmon. New York, N.Y., International Universities Press, 1976, 192 pp., no price listed.*

Lying, Despair, Jealousy, Envy, Sex, Suicide, Drugs, and the Good Life, *by Leslie H. Farber. New York, N.Y., Basic Books, 1976, 232 pp., $10.00.*

Practical Psychology, *by James P. Flanders. New York, N.Y., Harper & Row, 1976, 299 pp., no price listed.*

The Deadly Innocents: Portraits of Children Who Kill, *by Muriel Gardiner. New York, N.Y., Basic Books, 1976, 190 pp., $8.95.*

Psychotherapy with Children of Divorce, *by Richard A. Gardner, M.D. New York, N.Y., Jason Aronson, 1976, 528 pp., $25.00.*

Psychopharmacological Agents, Vol. IV: Use, Misuse, and Abuse, *edited by Maxwell Gordon. New York, N.Y., Academic Press (Harcourt Brace Jovanovich), 1976, 182 pp., $22.00.*

Biological Foundations of Psychiatry, Vols. 1 and 2, *edited by Robert G. Grenell and Sabit Gabay. New York, N.Y., Raven Press, 1976, 1,013 pp., $70.00 ($35.00 per volume).*

The Book of the It, *by Georg Groddeck, M.D. New York, N.Y., International Universities Press, 1976, 346 pp., no price listed.*

Recertification: A Look at the Issues. Report 96, *by the Group for the Advancement of Psychiatry Task Force on Recertification. New York, N.Y., GAP, 1976, 55 pp., $2.50 (paper).*

Psychoanalysis: Observation, Theory, Application. Selected Papers of Robert Waelder, *edited by Samuel A. Guttman, M.D., Ph.D. New York, N.Y., International Universities Press, 1976, 689 pp., no price listed.*

Studies in Violence and Television, *by Melvin S. Heller, M.S., M.D., and Samuel Polsky, J.D., Ph.D. New York, N.Y., American Broadcasting Co., 1976, 503 pp., no price listed (spiral bound).*

Disability in Childhood and Youth, *by P. Henderson, M.D., D.P.H. New York, N.Y., Oxford University Press, 1974, 195 pp., $3.75 (paper).*

Health Manpower Information for Policy Guidance, *edited by Dale L. Hiestand and Miriam Ostow. Cambridge, Mass., Ballinger Publishing Co. (J.B. Lippincott Co.), 1976, 138 pp., no price listed.*

Alternatives in Community Mental Health, *by Gordon P. Holleb and Walter H. Abrams. Boston, Mass., Beacon Press, 1975, 162 pp., $8.95.*

The Psychology of Death, concise ed., *by Robert Kastenbaum and Ruth Aisenberg. New York, N.Y., Springer Publishing Co., 1976, 434 pp., $9.95 (paper).*

The Mentally Retarded Citizen and the Law, *edited by Michael Kindred, Julius Cohen, David Penrod, and Thomas Shaffer; sponsored by the President's Committee on Mental Retardation. New York, N.Y., Free Press (Macmillan Publishing Co.), 1976, 692 pp., $18.95.*

Clinical Neuropharmacology, Vol. 1, *edited by Harold L. Klawans, M.D. New York, N.Y., Raven Press, 1976, 213 pp., $18.50.*

A Complete Guide to Therapy: From Psychoanalysis to Behavior Modification, *by Joel Kovel, M.D. New York, N.Y., Pantheon Books, 1976, 273 pp., $10.00.*

Community Survival for Long-Term Patients, *by H. Richard Lamb and associates. San Francisco, Calif., Jossey-Bass, 1976, 183 pp., $10.95.*

Approaches to Modifying Patient Behavior, *by Michael D. LeBow, Ph.D. New York, N.Y., Appleton-Century-Crofts (Prentice-Hall), 1976, 372 pp., no price listed.*

Handbook of Behavior Modification and Behavior Therapy, *edited by Harold Leitenberg. Englewood Cliffs, N.J., Prentice-Hall, 1976, 649 pp., no price listed.*

Drug Use and Abuse Among U.S. Minorities: An Annotated Bibliography, *by Patti Iiyama, Setsuko Matsunaga Nishi, and Bruce D. Johnson. New York, N.Y., Praeger Publishers, 1976, 247 pp., $15.00.*

Ego Development, *by Jane Loevinger, with the assistance of Augusto Blasi. San Francisco, Calif., Jossey-Bass, 1976, 482 pp., $17.50.*

Kindly Bent To Ease Us, Part Two: Meditation, *by Longchenpa; translated and annotated by Herbert V. Guenther. Emeryville, Calif., Dharma Publishing, 1976, 118 pp., $4.95 (paper).*

Getting To Know the Troubled Child, *by David H. Looff, M.D. Knoxville, Tenn., University of Tennessee Press, 1976, 241 pp., $5.95 (paper).*

Psychiatrie und Psychosomatik: Gedenkschrift für Prof. N. Petrilowitsch, *edited by J.J. López Ibor, R. Michaelis, and U. Spiegelberg. New York, N.Y., S. Karger, 1976, 191 pp., $34.00 (paper).*

Murder and Madness, *by Donald T. Lunde. San Francisco, Calif., San Francisco Book Co., 1976, 133 pp., $3.95 (paper).*

Psychological Assessment: A Conceptual Approach, *by Michael P. Maloney, Ph.D., and Michael P. Ward, Ph.D. New York, N.Y., Oxford University Press, 1976, 408 pp., $14.00.*

People and Predicaments, *by Milton Mazer. Cambridge, Mass., Harvard University Press, 1976, 275 pp., $12.50.*

The Psychiatric Hospital Today—A Quality Profile, *by John Mulhearn and Gayle Momeny. Cambridge, Mass., Ballinger Publishing Co. (J.B. Lippincott Co.), 1976, 138 pp., no price listed.*

Multidimensional Functional Assessment: The OARS Methodology. A Manual, *edited by Eric Pfeiffer, M.D. Durham, N.C., Center for the Study of Aging and Human Development, 1975, 134 pp., $6.00 (paper).*

Heroin Addiction: Theory, Research, and Treatment, *by Jerome J. Platt and Christina Labate. New York, N.Y., Wiley-Interscience (John Wiley & Sons), 1976, 398 pp., $19.95.*

Freud's "Project" Re-Assessed: Preface to Contemporary Cognitive Theory and Neuropsychology, *by Karl H. Pribram and Merton M. Gill. New York, N.Y., Basic Books, 1976, 181 pp., $10.00.*

Autism: Diagnosis, Current Research and Management, *edited by Edward R. Ritvo, M.D., Betty Jo Freeman, Ph.D., Edward M. Ornitz, M.D., and Peter E. Tanguay, M.D. Holliswood, N.Y., Spectrum Publications (New York, N.Y., Halsted Press, John Wiley & Sons, distributor), 1976, 298 pp., $16.95.*

Creative Art Therapy, *by Arthur Robbins, Ed.D., A.T.R., and Linda Beth Sibley, M.P.S., A.T.R. New York, N.Y., Brunner/Mazel, 1976, 261 pp., $15.00.*

Génétique et Comportements, *by Pierre Roubertoux and Michèle Carlier. Paris, France, Masson, 1976, 223 pp., 70 French francs (paper).*

Freedom To Die: Moral and Legal Aspects of Euthanasia, *by O. Ruth Russell. New York, N.Y., Laurel (Dell Publishing Co.), 1976, 316 pp., $1.95 (paper).*

Hormones, Behavior, and Psychopathology, *edited by Edward J. Sachar, M.D. New York, N.Y., Raven Press, 1976, 300 pp., $24.00.*

Parapsychology: Its Relation to Physics, Biology, Psychology, and Psychiatry, *edited by Gertrude R. Schmeidler. Metuchen, N.J., Scarecrow Press, 1976, 263 pp., $11.00.*

Understanding EEG: An Introduction to Electroencephalography, *by Donald Scott. Philadelphia, Pa., J.B. Lippincott Co., 1976, 241 pp., $16.00.*

Suicidology: Contemporary Developments, *edited by Edwin S. Shneidman, Ph.D. New York, N.Y., Grune & Stratton (Harcourt Brace Jovanovich), 1976, 546 pp., no price listed.*

Social Deviance, *by S. Giora Shoham. New York, N.Y., Gardner Press (Halsted Press, John Wiley & Sons, distributor), 1976, 160 pp., $13.95.*

Systems of Family and Marital Psychotherapy, *by A.C. Robin Skynner, M.D., D.P.M. New York, N.Y., Brunner/Mazel, 1976, 418 pp., $17.95.*

Psychoanalysis and Contemporary Science: An Annual of Integrative and Interdisciplinary Studies, Vol. IV, 1975, *edited by Donald P. Spence. New York, N.Y., International Universities Press, 1976, 567 pp., no price listed.*

Philosophical Dimensions of the Neuro-Medical Sciences, *edited by Stuart F. Spicker and H. Tristram Engelhardt, Jr. Lawrence, Mass., D. Reidel Publishing Co., 1976, 268 pp., $29.00.*

Treatment of the Narcissistic Neuroses, *by Hyman Spotnitz, M.D., Med.Sc.D., and Phyllis W. Meadow, Ph.D. New York, N.Y., Manhattan Center for Advanced Psychoanalytic Studies, 1976, 246 pp., $15.00.*

The Adventure of Sobriety, *by David A. Stewart. East Lansing, Mich., Michigan State University Press, 1976, 128 pp., $7.50.*

The Psychological World of Natsume Sōseki, *by Doi Takeo; translated by William Jefferson Tyler. Cambridge, Mass., Harvard University Press, 1976, 158 pp., $15.00.*

Acupuncture Therapy: Current Chinese Practice, 2nd ed., *by Leong T. Tan, Margaret Y.-C. Tan, and Ilza Veith. Philadelphia, Pa., Temple University Press, 1976, 250 pp., $17.50.*

Alcoholism: Interdisciplinary Approaches to an Enduring Problem, *edited by Ralph E. Tarter and A. Arthur Sugerman. Reading, Mass., Addison-Wesley Publishing Co. Advanced Book Program, 1976, 852 pp., $13.50 (paper).*

The Freudian Slip: Psychoanalysis and Textual Criticism, *by Sebastiano Timpanaro; translated by Kate Soper. Atlantic Highlands, N.J., Humanities Press, 1976, 225 pp., $13.50.*

Family Constellation: Its Effects on Personality and Social Behavior, 3rd ed., *by Walter Toman, Ph.D. New York, N.Y., Springer Publishing Co., 1976, 325 pp., $12.95.*

Differential Diagnosis and Treatment in Social Work, 2nd ed., *edited by Francis J. Turner. New York, N.Y., Free Press (Macmillan Publishing Co.), 1976, 758 pp., $15.95.*

The Role of Bodily Feelings in Anxiety. Maudsley Monograph 23, *by Peter Tyrer. New York, N.Y., Oxford University Press, 1976, 119 pp., $18.00.*

Environments as Therapy for Brain Dysfunction, *edited by Roger N. Walsh and William T. Greenough. New York, N.Y., Plenum Press, 1976, 369 pp., $29.50.*

Waking Dreams, *by Mary M. Watkins. New York, N.Y., Interface (Gordon and Breach), 1976, 168 pp., $17.50.*

The Neurosciences: Paths of Discovery, *edited by Frederic G. Worden, Judith P. Swazey, and George Adelman. Cambridge, Mass., MIT Press, 1975, 587 pp., $14.95 (paper).*

Mental Retardation and Developmental Disabilities: An Annual Review, VIII, *edited by Joseph Wortis, M.D. New York, N.Y., Brunner/Mazel, 1976, 332 pp., $17.50.*

Psychodrama: Resolving Emotional Problems Through Role-Playing, *by Lewis Yablonsky. New York, N.Y., Basic Books, 1976, 285 pp., $10.95.*

No default insurance

Tofranil-PM®
imipramine **pamoate**

Geigy

In depression

Daily Dosage Chart

1 h.s.

A major reason for drug defaulting is multiple daily dosage schedules.

Ayd* reports that 70 percent of patients default on a q.i.d. regimen; 60 percent on t.i.d.; 30 percent on b.i.d., and only 7 percent on a single daily dose.

A single daily capsule that provides a full day's medication would logically assure better therapeutic results.

Because one capsule lasts from bedtime to bedtime, Tofranil-**PM**® may markedly reduce the probability of missed doses.

After therapy is initiated with the 75-mg. capsule, the 150-mg. capsule is the dose level at which optimum response is usually obtained.

Please review the prescribing information summarized on the back of this page.

*Ayd, F.J., Jr. (Ed.): Int. Drug Ther. Newslett. 7(9/10):35-50 (Nov./Dec.) 1972.

Tofranil-PM®
imipramine **pamoate**

One capsule
lasts from bedtime
to bedtime.

Initial Dose

For Maintenance Therapy

Starting Dose	Usual Optimum Response Dose	A Full Range to Choose From*			
					
75 mg.	150 mg.	150 mg.	125 mg.	100 mg.	75 mg.

***Each capsule contains imipramine pamoate equivalent to 150, 125, 100 or 75 mg. imipramine hydrochloride.**

Tofranil-PM®
brand of imipramine pamoate

Indications: For the relief of symptoms of depression. Endogenous depression is more likely to be alleviated than other depressive states.

Contraindications: The concomitant use of monoamine oxidase inhibiting compounds is contraindicated. Hyperpyretic crises or severe convulsive seizures may occur in patients receiving such combinations. The potentiation of adverse effects can be serious, or even fatal. When it is desired to substitute Tofranil-PM, brand of imipramine pamoate, in patients receiving a monoamine oxidase inhibitor, as long an interval should elapse as the clinical situation will allow, with a minimum of 14 days. Initial dosage should be low and increases should be gradual and cautiously prescribed. The drug is contraindicated during the acute recovery period after a myocardial infarction. Patients with a known hypersensitivity to this compound should not be given the drug. The possibility of cross-sensitivity to other dibenzazepine compounds should be kept in mind.

Warnings: *Usage in Pregnancy:* Safe use of imipramine during pregnancy and lactation has not been established; therefore, in administering the drug to pregnant patients, nursing mothers, or women of childbearing potential, the potential benefits must be weighed against the possible hazards. Animal reproduction studies have yielded inconclusive results. There have been clinical reports of congenital malformation associated with the use of this drug, but a causal relationship has not been confirmed.

Extreme caution should be used when this drug is given to:

—patients with cardiovascular disease because of the possibility of conduction defects, arrhythmias, myocardial infarction, strokes and tachycardia;

—patients with increased intraocular pressure, history of urinary retention, or history of narrow-angle glaucoma because of the drug's anticholinergic properties;

—hyperthyroid patients or those on thyroid medication because of the possibility of cardiovascular toxicity;

—patients with a history of seizure disorder because this drug has been shown to lower the seizure threshold;

—patients receiving guanethidine or similar agents since imipramine may block the pharmacologic effects of these drugs.

Since imipramine may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as operating an automobile or machinery, the patient should be cautioned accordingly.

Usage in Children: Tofranil-PM, brand of imipramine pamoate, should not be used in children of any age because of the increased potential for acute overdosage due to the high unit potency (75 mg., 100 mg., 125 mg. and 150 mg.). Each capsule contains imipramine pamoate equivalent to 75 mg., 100 mg., 125 mg. or 150 mg. imipramine hydrochloride.

Precautions: It should be kept in mind that the possibility of suicide in seriously depressed patients is inherent in the illness and may persist until significant remission occurs. Such patients should be carefully supervised during the early phase of treatment with Tofranil-PM, brand of imipramine pamoate, and may require hospitalization. Prescriptions should be written for the smallest amount feasible.

Hypomanic or manic episodes may occur, particularly in patients with cyclic disorders. Such reactions may necessitate discontinuation of the drug. If needed, Tofranil-PM, brand of imipramine pamoate, may be resumed in lower dosage when these episodes are relieved. Administration of a tranquilizer may be useful in controlling such episodes.

Prior to elective surgery, imipramine should be discontinued for as long as the clinical situation will allow.

An activation of the psychosis may occasionally be observed in schizophrenic patients and may require reduction of dosage and the addition of a phenothiazine.

In occasional susceptible patients or in those receiving anticholinergic drugs (including antiparkinsonism agents) in addition, the atropine-like effects may become more pronounced (e.g., paralytic ileus). Close supervision and careful adjustment of dosage is required when this drug is administered concomitantly with anticholinergic or sympathomimetic drugs.

Avoid the use of preparations, such as decongestants and local anesthetics, which contain any sympathomimetic amine (e.g., adrenalin, noradrenalin), since it has been reported that tricyclic antidepressants can potentiate the effects of catecholamines.

Patients should be warned that the concomitant use of alcoholic beverages may be associated with exaggerated effects.

Both elevation and lowering of blood sugar levels have been reported.

Concurrent administration of imipramine with electroshock therapy may increase the hazards; such treatment should be limited to those patients for whom it is essential, since there is limited clinical experience.

Adverse Reactions: Note: Although the listing which follows includes a few adverse reactions which have not been reported with this specific drug, the pharmacological similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when imipramine is administered.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke, falls.

Psychiatric: Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurological: Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alterations in EEG patterns; tinnitus.

Anticholinergic: Dry mouth, and, rarely, associated sublingual adenitis; blurred vision, disturbances of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

Allergic: Skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight); edema (general or of face and tongue); drug fever; cross-sensitivity with desipramine.

Hematologic: Bone marrow depression including agranulocytosis; eosinophilia; purpura; thrombocytopenia. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathological neutrophil depression.

Gastrointestinal: Nausea and vomiting, anorexia, epigastric distress, diarrhea; peculiar taste, stomatitis, abdominal cramps, black tongue.

Endocrine: Gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood sugar levels.

Other: Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency; drowsiness, dizziness, weakness and fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: Though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache and malaise.

Dosage and Administration: In adult outpatients, therapy should be initiated on a once-a-day basis with 75 mg./day. This may be increased to 150 mg./day which is the dose level which usually obtains optimum response. If necessary, dosage may be increased to 200 mg./day. Dosage should be modified as necessary by clinical response and any evidence of intolerance. Daily dosage may be given at bedtime, or in some patients in divided daily doses.

Hospitalized patients should be started on a once-a-day basis with 100-150 mg./day and may be increased to 200 mg./day. Dosage should be increased to 250-300 mg./day if there is no response after two weeks.

Following remission, maintenance medication may be required for a longer period of time at the lowest dose that will maintain remission. The usual adult maintenance dosage is 75-150 mg./day on a once-a-day basis, preferably at bedtime.

In adolescent and geriatric patients, capsules of Tofranil-PM, brand of imipramine pamoate, may be used when total daily dosage is established at 75 mg. or higher. It is generally unnecessary to exceed 100 mg./day in these patients. This dosage may be given once a day at bedtime or, if needed, in divided daily doses.

How Supplied: Tofranil-PM, brand of imipramine pamoate: Capsules of 75, 100, 125 and 150 mg. (Each capsule contains imipramine pamoate equivalent to 75, 100, 125 or 150 mg. of imipramine hydrochloride.)

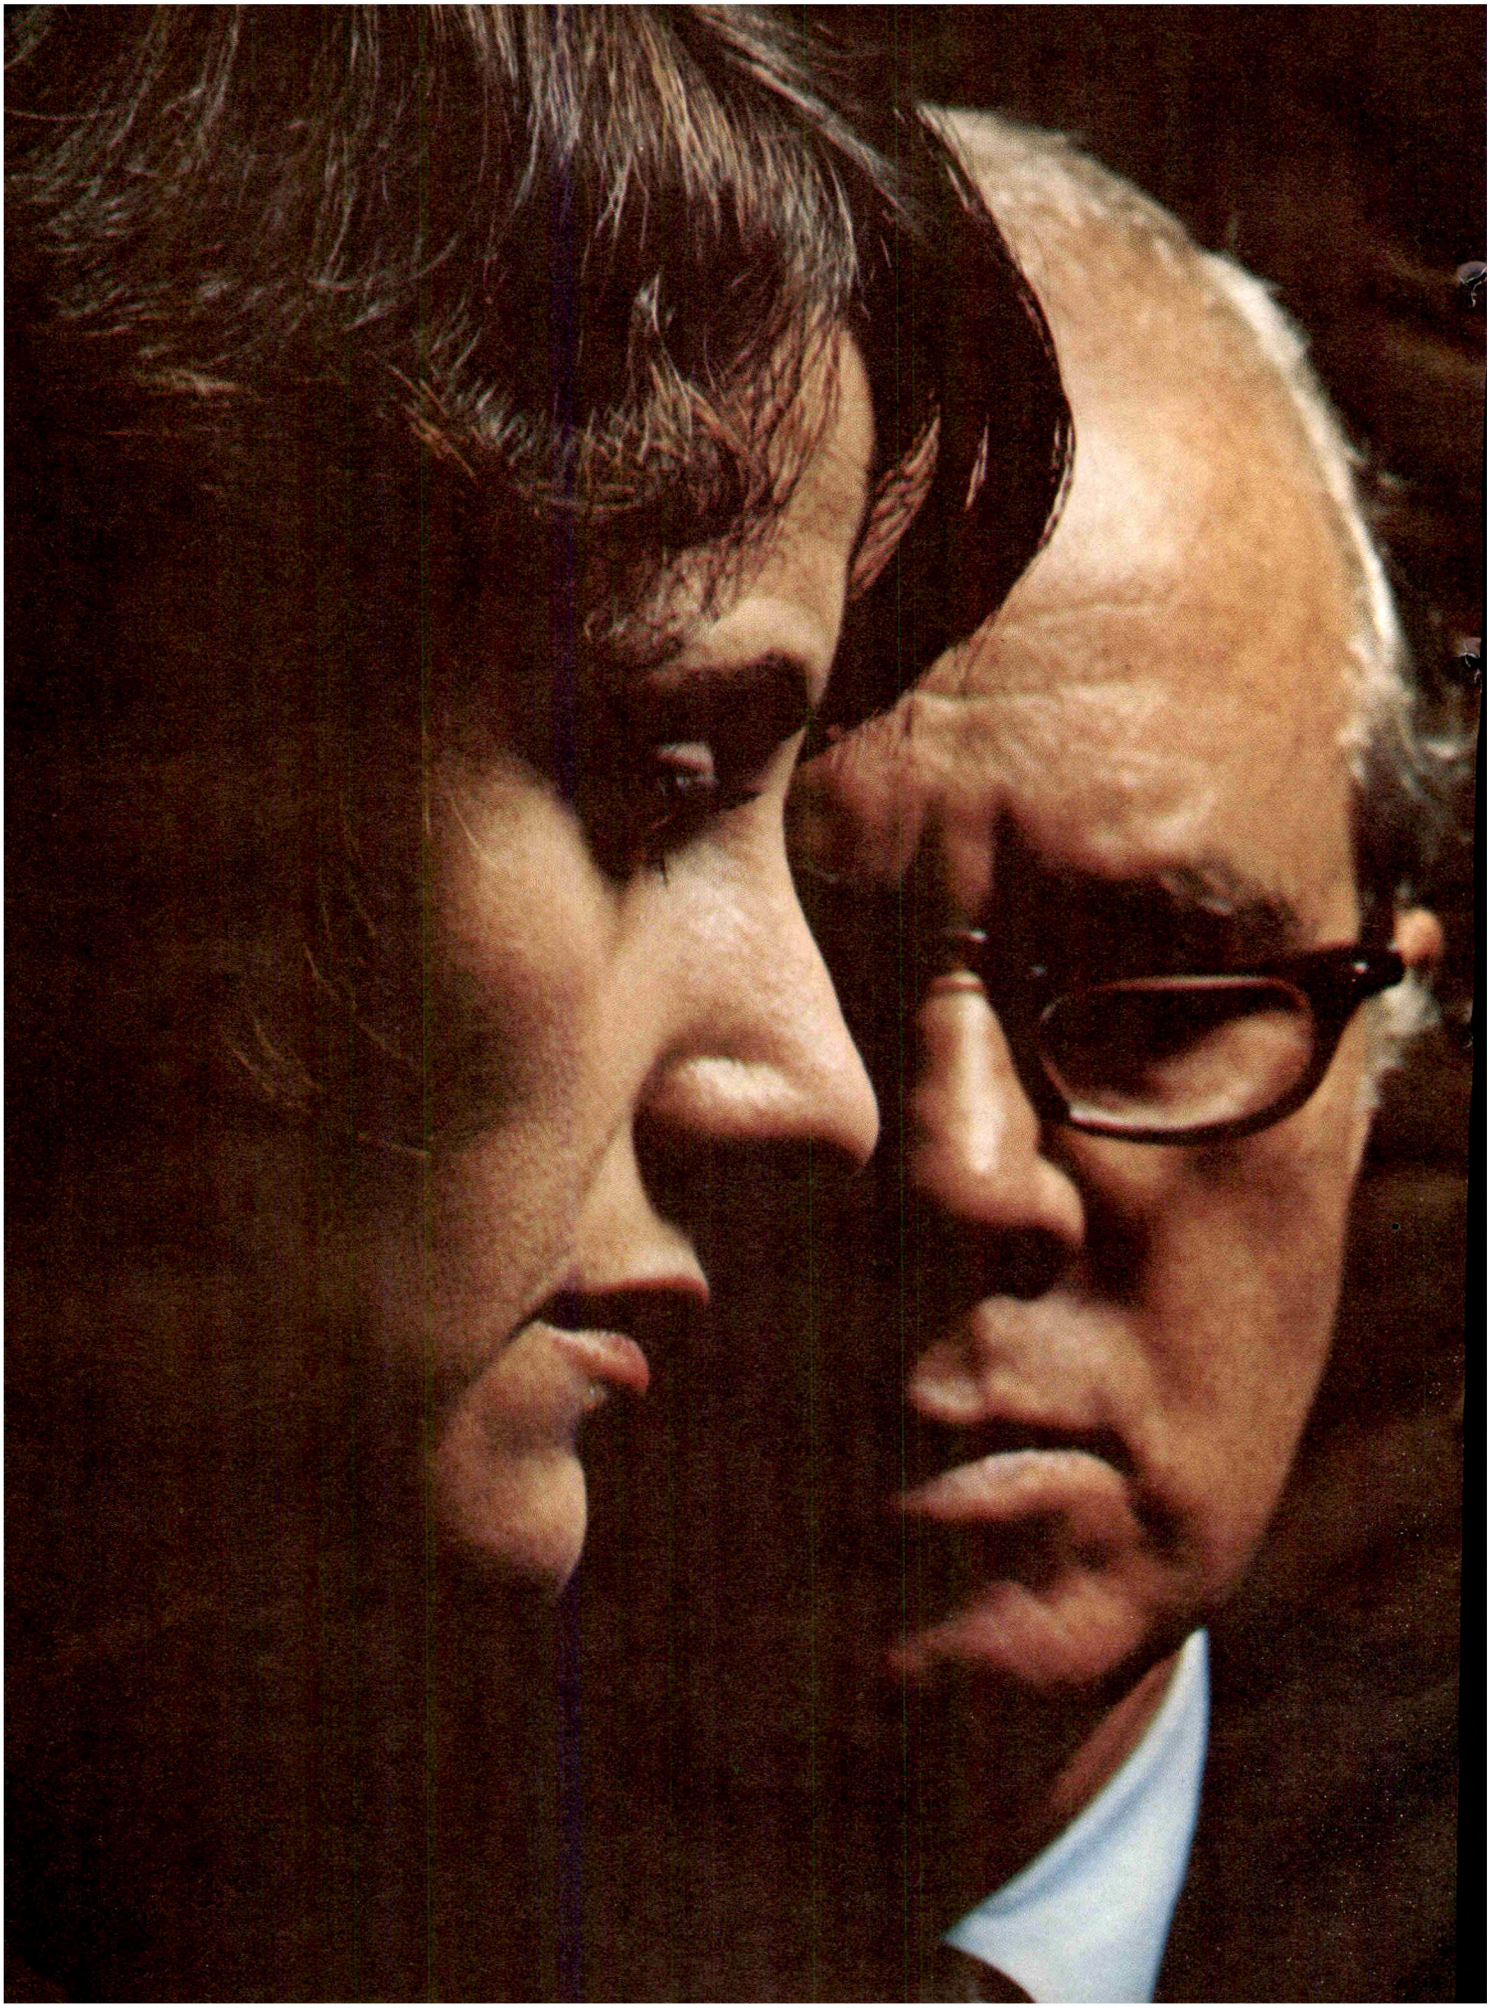
First Time Available at

The Institute on Hospital & Community Psychiatry

Marriott Hotel Atlanta, Georgia September 20-23

APA PLACEMENT SERVICE



For Employers and Position Applicants

Those wishing to announce either position openings or their availability for employment may register in advance by requesting a listing form by calling Ms. M. J. Merrick (202) 232-7878, Ext. 327, or writing to her attention at APA Central Office, Membership Services Division, 1700 18th St., N.W. Washington, D.C. 20009. Forms should be returned no later than September 15th. On-site listings will also be accepted. However, listings received at the APA prior to September 15th will be available from the very beginning of the Institute. There will be a placement booth and an interviewing area located in the Institute registration area at the Marriott Hotel. Listings will be accepted for any mental health related position vacancy/position availability.

Applicants – $3 for listing availability.

Employers – $5 for listing job description.

Complete sets of all applicant and position listings will be available at the close of the meeting at $10 per set.

The TRIAVIL® Potential in the management of moderate to severe anxiety with depression

When time and talk are not enough...
The therapist is the primary catalyst for change in the psychotherapeutic relationship. However, when patients suffer from moderate to severe anxiety with depression, there are situations when TRIAVIL can often be a useful adjunct.

...TRIAVIL may help
There are three important benefits you may expect when TRIAVIL is part of the treatment program: (1) When symptoms of moderate to severe anxiety or agitation with depression are relieved, the patient may become more accessible and cooperative. (2) As somatic manifestations are controlled, attention may be focused on underlying causative factors. (3) Symptomatic relief may enable the patient to function more effectively in his daily life while your work with the patient progresses.

Tablets TRIAVIL are available in four different combinations affording flexibility and individualized dosage adjustment. Since it is simpler to remember to take one tablet rather than several (particularly in multiple daily doses), your patients on TRIAVIL will be more likely to take proper doses of the medication.

TRIAVIL is contraindicated in CNS depression from drugs; in the presence of evidence of bone marrow depression; and in patients hypersensitive to phenothiazines or amitriptyline. It should not be used during the acute recovery phase following myocardial infarction or in patients who have received an MAOI within two weeks. Patients with cardiovascular disorders should be watched closely. Not recommended in children or during pregnancy. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol. Antiemetic effect may obscure toxicity due to other drugs or mask other disorders. Since suicide is a possibility in any depressive illness, patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

MSD
MERCK SHARP & DOHME

For a brief summary of prescribing information, please turn to the following page.

when patients exhibit moderate to marked anxiety or agitation with symptoms of depression

TRIAVIL® **containing perphenazine and amitriptyline HCl**

a tranquilizer-antidepressant

for highly effective relief of depression with moderate anxiety

TRIAVIL®

containing perphenazine and amitriptyline HCl

a tranquilizer-antidepressant

Available:

TRIAVIL® 2-25: Each tablet contains 2 mg perphenazine and 25 mg amitriptyline HCl

TRIAVIL® 2-10: Each tablet contains 2 mg perphenazine and 10 mg amitriptyline HCl

TRIAVIL® 4-25: Each tablet contains 4 mg perphenazine and 25 mg amitriptyline HCl

TRIAVIL® 4-10: Each tablet contains 4 mg perphenazine and 10 mg amitriptyline HCl

INITIAL THERAPY FOR MANY PATIENTS
TRIAVIL® 2-25 (or TRIAVIL® 4-25) t.i.d. or q.i.d.

FOR FLEXIBILITY IN ADJUSTING MAINTENANCE THERAPY
TRIAVIL® 2-10 (or TRIAVIL® 4-10)

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, alcohol, narcotics, analgesics, antihistamines); bone marrow depression; known hypersensitivity to phenothiazines or amitriptyline. Do not give concomitantly with MAOI drugs because hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. Allow minimum of 14 days between therapies, then initiate therapy with TRIAVIL cautiously, with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction.

WARNINGS: TRIAVIL should not be given with guanethidine or similarly acting compounds. Use cautiously in patients with history of urinary retention, angle-closure glaucoma, increased intraocular pressure, or convulsive disorders. In patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, particularly in high doses, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. Caution patients performing hazardous tasks, such as operating machinery or driving motor vehicles, that drug may impair mental and/or physical abilities. Not recommended in children or during pregnancy.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.

Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of untoward actions is greater with high doses. Closely supervise with any dosage. The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction. A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.

If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine. Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides.

Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant. Patients with paranoid symptomatology may have an exaggeration of such symptoms. The tranquilizing effect of TRIAVIL seems to reduce the likelihood of this effect. When amitriptyline HCl is given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. Paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs.

Caution is advised if patients receive large doses of ethchlorvynol concurrently. Transient delirium has been reported in patients who were treated with 1 g of ethchlorvynol and 75-150 mg of amitriptyline HCl.

Amitriptyline HCl may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.

Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards associated with such therapy. Such treatment should be limited to patients for whom it is essential. Discontinue several days before elective surgery if possible. Elevation and lowering of blood sugar levels have both been reported. Use with caution in patients with impaired liver function.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.

Perphenazine: Side effects may be any of those reported with phenothiazine drugs: extrapyramidal symptoms (opisthotonus, oculogyric crisis, hyperreflexia, dystonia, akathisia, acute dyskinesia, ataxia, parkinsonism) can usually be controlled by the concomitant use of effective antiparkinsonian drugs and/or by reduction in dosage, but sometimes persist after discontinuation of the phenothiazine.

Tardive dyskinesia may appear in some patients on long-term therapy or may occur after drug therapy with phenothiazines and related agents has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. Symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Involuntary movements of the extremities sometimes occur. There is no known treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms. It is advised that all antipsychotic agents be discontinued if the above symptoms appear. If treatment is reinstituted, or dosage of the particular drug increased, or another drug substituted, the syndrome may be masked. It has been suggested that fine vermicular movements of the tongue may be an early sign of the syndrome, and that the full-blown syndrome may not develop if medication is stopped when lingual vermiculation appears.

Other side effects are skin disorders (photosensitivity, itching, erythema, urticaria, eczema, up to exfoliative dermatitis); other allergic reactions (asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions); peripheral edema; reversed epinephrine effect; hyperglycemia; endocrine disturbances (lactation, galactorrhea, gynecomastia, disturbances of menstrual cycle); altered cerebrospinal fluid proteins; paradoxical excitement; hypertension, hypotension, tachycardia, and ECG abnormalities (quinidine-like effect); reactivation of psychotic processes; catatonic-like states; autonomic reactions, such as dry mouth or salivation, headache, anorexia, nausea, vomiting, constipation, obstipation, urinary frequency or incontinence, blurred vision, nasal congestion, and a change in pulse rate; hypnotic effects; pigmentary retinopathy; corneal and lenticular pigmentation; occasional lassitude, muscle weakness, mild insomnia. Other adverse reactions reported with various phenothiazine compounds include blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosinophilia); liver damage (jaundice, biliary stasis); grand mal convulsions; cerebral edema; polyphagia; photophobia; skin pigmentation; and failure of ejaculation.

Amitriptyline: Note: Listing includes a few reactions not reported for this drug, but which have occurred with other pharmacologically similar tricyclic antidepressant drugs. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpitation; myocardial infarction; arrhythmias; heart block; stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth; blurred vision; disturbance of accommodation; constipation; paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic:* Skin rash; urticaria; photosensitization; edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastric distress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; parotid swelling; black tongue. Rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido; elevated or lowered blood sugar levels. *Other:* Dizziness; weakness; fatigue; headache; weight gain or loss; increased perspiration; urinary frequency; mydriasis; drowsiness; alopecia. *Withdrawal Symptoms:* Abrupt cessation after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

OVERDOSAGE: All patients suspected of having taken an overdosage should be admitted to a hospital as soon as possible. Treatment is symptomatic and supportive. However, the intravenous administration of 1–3 mg of physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage of physostigmine should be repeated as required particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine. On this basis, in severe overdosage with perphenazine-amitriptyline combinations, symptomatic treatment of central anticholinergic effects with physostigmine salicylate should be considered.

Coverage and Utilization of Care for Mental Conditions Under Health Insurance —Various Studies, 1973–74

By Louis S. Reed, Ph.D.
Consultant in Health Economics, American Psychiatric Association

This book reports six studies that add to the growing body of data demonstrating the feasibility of covering mental illness under health insurance. Although in some ways it may be considered a supplement to APA's 1972 book **HEALTH INSURANCE AND PSYCHIATRIC CARE: UTILIZATION AND COST** (Reed, Myers, and Scheidemandel), all of the data are new. The studies cover the following areas:

- Utilization of mental benefits under the Blue Cross and Blue Shield plan for federal employees, documenting that a "plateau" in the use of these benefits was reached in 1973–74.
- Comparison of benefits for mental and other illnesses under selected employee health benefit plans.
- Coverage of mental illness under collective bargaining agreements of selected unions.
- Utilization of care for mental conditions under the Canadian health insurance program, which gives the same coverage for mental as for other conditions.
- Updating of information on Blue Cross benefits for hospital care of mental illness.
- Data from selected Blue Cross and Blue Shield plans on coverage and utilization of mental conditions, with emphasis on major medical coverage.

If you think adjunctive antianxiety therapy is indicated...

Consider Serax® (oxazepam). It has been proved useful when anxiety and tension aren't responsive to simple reassurance and counsel.

Serax has been found valuable, particularly in the older patient, in the management and control of clinically significant anxiety, tension, agitation and irritability. It may also be useful where anxiety accompanies an underlying organic disorder.

Of special importance to elderly patients, Serax may be taken generally without fear of serious side effects.* Its dosage flexibility† generally permits adjustment to individual patient needs, making Serax a convenient adjunct to your therapy in the older patient.

Special care must, of course, be taken in prescribing antianxiety agents for elderly patients, especially where cardiac complications might ensue from a drop in blood pressure. And careful attention must be paid to dosage recommendations and follow-up observation.

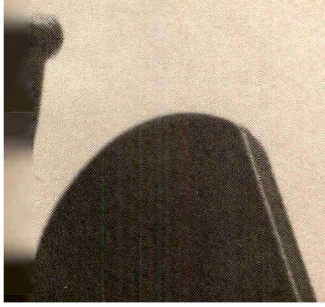
*See following important information.
†See package circular for full prescribing information.

In Brief:

Indications: Oxazepam is indicated for the management and control of anxiety, tension, agitation, irritability and related symptoms. Such symptoms are commonly seen in patients with a diagnosis of psychoneurotic reaction, psychophysiological reaction, personality disorder, or in patients with underlying organic disease. Anxiety associated with depression is also responsive to oxazepam therapy. This product has been found particularly useful in the management of anxiety, tension, agitation and irritability in older patients. Alcoholics with acute tremulousness, inebriation or with anxiety associated with alcohol withdrawal are responsive to therapy.

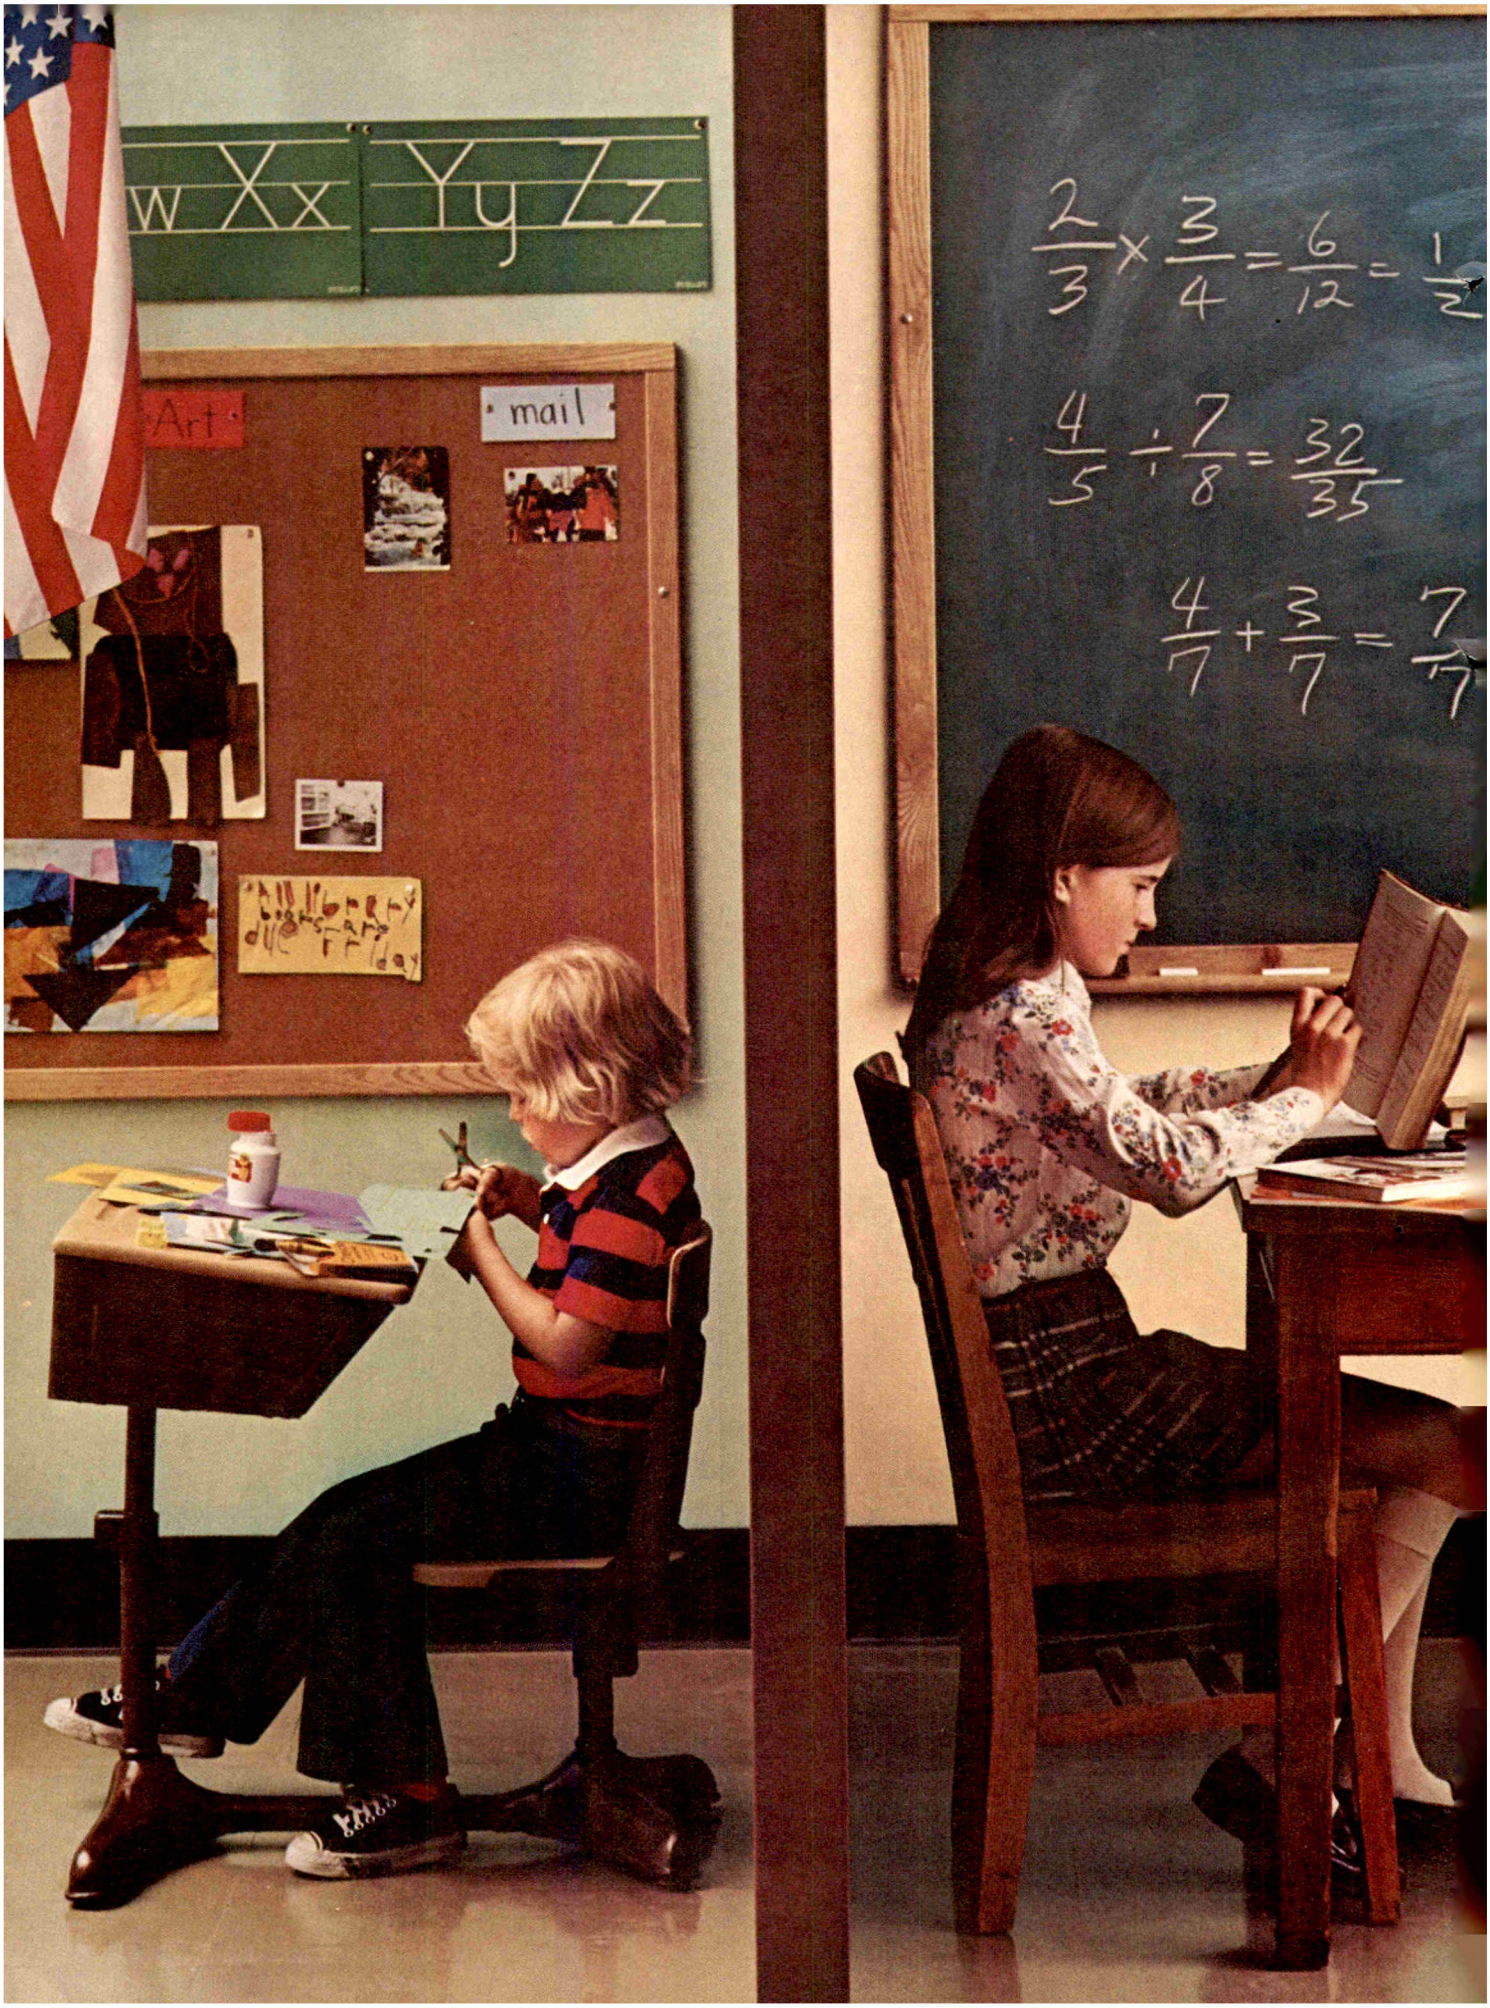
Contraindications: History of previous hypersensitivity to oxazepam. Oxazepam is not indicated in psychoses.

Warning: Use in Pregnancy: Safety for use in pregnancy not established.



Precautions: Hypotensive reactions are rare, but use with caution where cardiac complications could ensue from a fall in blood pressure, especially in the elderly. Withdrawal symptoms upon discontinuation have been noted in some patients exhibiting drug dependence through chronic overdose. Carefully supervise dose and amounts prescribed, especially for patients prone to self-overdose; excessive, prolonged use in susceptible patients (alcoholics, ex-addicts, etc.) may result in dependence or habituation. Reduce dosage gradually after prolonged excessive dosage to avoid possible epileptiform seizures. Withdrawal symptoms following abrupt discontinuance are similar to those seen with barbiturates. Caution patients against driving or operating machinery until absence of drowsiness or dizziness is ascertained. Warn patients of possible reduction in alcohol tolerance. Not indicated in children under 6 years; absolute dosage for 6- to 12-year olds not established.

Adverse Reactions: Therapy-interrupting side effects are rare. Transient mild drowsiness is common initially; if persistent, reduce dosage. Dizziness, vertigo and headache have also occurred infrequently; syncope, rarely. Mild paradoxical reactions (excitement, stimulation of affect) are reported in psychiatric patients. Minor diffuse rashes (morbilliform, urticarial and maculopapular) are rare. Nausea, lethargy, edema, slurred speech, tremor and altered libido are rare and generally controllable by dosage reduction. Although rare, leukopenia and hepatic dysfunction including jaundice have been reported during therapy. Periodic blood counts and liver function tests are advised. Ataxia, reported rarely, does not appear related to dose or age. These side reactions, noted with related compounds, are not yet reported: paradoxical excitation with severe rage reactions, hallucinations, menstrual irregularities, change in EEG pattern, blood dyscrasias (including agranulocytosis), blurred vision, diplopia, incontinence, stupor, disorientation, fever and euphoria.



Availability: Capsules of 10, 15 and 30 mg. oxazepam; tablets of 15 mg. oxazepam.

In clinically significant anxiety

The vulnerable ages

The first epileptic seizure is most likely to occur during early childhood and at the onset of puberty

About 9 out of 10 epileptics experience their first seizure before the age of 20—with the highest incidence between 5 and 7, when children start school, and at the onset of puberty, a time of physiological and psychic turmoil.[1] The most common type, grand mal, occurs in approximately 75% of epileptic children,[1] and more than 50% of patients who suffer initially from petit mal develop grand mal seizures before they reach the age of 16.[2]

Mysoline (primidone) for control of grand mal, psychomotor and focal epilepsy

At the onset and afterwards — used alone or as concomitant therapy, MYSOLINE may reduce the frequency and severity of major motor seizures—or even eliminate them. *Excellent* for control of grand mal. Valuable for control of psychomotor[1,3,4] and focal epilepsy as well.[5]

Add Mysoline when control with other anticonvulsants is inadequate — As concomitant therapy, MYSOLINE can improve seizure control in grand mal and psychomotor epilepsy. The combined use of phenobarbital, diphenylhydantoin, and MYSOLINE may have additive anticonvulsant effects without additive side effects.[6]

Change to Mysoline when other anticonvulsants fail — A changeover to MYSOLINE is frequently warranted when other anticonvulsants must be discontinued because of important side effects, or when grand mal seizures are refractory to phenobarbital, with or without diphenylhydantoin.[7]

Mysoline® (primidone)

may be the start of a better life for the epileptic

initial and maintenance therapy for
grand mal, psychomotor and focal epilepsy

BRIEF SUMMARY
(For full prescribing information, see package circular.)

MYSOLINE® Brand of PRIMIDONE

Anticonvulsant

ACTIONS: MYSOLINE acts on the central nervous system to raise seizure threshold or alter seizure pattern. The mechanism(s) of action of anticonvulsant drugs is not known.

Primidone has anticonvulsant activity *per se*. In addition, its two metabolites possess anticonvulsant qualities. The major metabolite is phenylethylmalonamide (PEMA); the other is phenobarbital. In addition to its own anticonvulsant potential, PEMA potentiates phenobarbital.

INDICATIONS: MYSOLINE, either alone or used concomitantly with other anticonvulsants, is indicated in the control of grand mal, psychomotor, and focal epileptic seizures. It may control grand mal seizures refractory to other anticonvulsant therapy.

CONTRAINDICATIONS: Primidone is contraindicated in: 1) patients with porphyria and 2) patients who are hypersensitive to phenobarbital (see ACTIONS).

WARNINGS: The abrupt withdrawal of antiepileptic medication may precipitate status epilepticus.

The therapeutic efficacy of a dosage regimen takes several days before it can be assessed.

Use in pregnancy: Recent reports strongly suggest an association between the use of anticonvulsant drugs by women with epilepsy and an elevated incidence of birth defects in children born to these women. Reference has been made to primidone in several cases in which it was used *in combination* with other anticonvulsants; but its teratogenicity has not been conclusively demonstrated. The possibility exists that other factors, *e.g.*, genetic factors or the epileptic condition, may contribute to the higher incidence of birth defects. The data also indicate that the great majority of mothers receiving anticonvulsant medication deliver normal infants.

Anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and risk to both mother and the unborn child.

When the nature, frequency, and severity of the seizures do not pose a clear threat to the patient, good medical practice requires that the physician weigh the expected therapeutic benefit of anticonvulsant therapy against possible risk on an individual basis.

Neonatal hemorrhage, with a coagulation defect resembling vitamin K deficiency, has been described in newborns whose mothers were taking primidone and other anticonvulsants. Pregnant women under anticonvulsant therapy should receive prophylactic vitamin K_1 therapy for one month prior to, and during, delivery.

The physician should weigh all of the foregoing considerations when treating and counseling epileptic women of childbearing potential.

PRECAUTIONS: The total daily dosage should not exceed 2 Gm. Since MYSOLINE therapy generally extends over prolonged periods, a complete blood count and a sequential multiple analysis-12 (SMA-12) test should be made every six months.

In nursing mothers: There is evidence that in mothers treated with primidone, the drug appears in the milk in substantial quantities. Since tests for the presence of primidone in biological fluids are too complex to be carried out in the average clinical laboratory, it is suggested that the presence of undue somnolence and drowsiness in nursing newborns of MYSOLINE-treated mothers be taken as an indication that nursing should be discontinued.

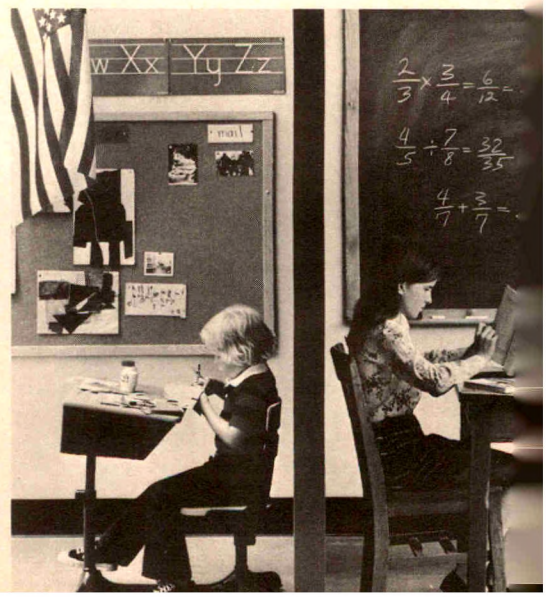
ADVERSE REACTIONS: The most frequently occurring early side effects are ataxia and vertigo. These tend to disappear with continued therapy, or with reduction of initial dosage. Occasionally, the following have been reported: nausea, anorexia, vomiting, fatigue, hyperirritability, emotional disturbances, sexual impotency, diplopia, nystagmus, drowsiness, and morbilliform skin eruptions. Occasionally, persistent or severe side effects may necessitate withdrawal of the drug. Megaloblastic anemia may occur as a rare idiosyncrasy to MYSOLINE and to other anticonvulsants. The anemia responds to folic acid, 15 mg. daily, without necessity of discontinuing medication.

DOSAGE AND ADMINISTRATION: The average adult dose is 0.75 to 1.5 Gm. per day. The initial dose is 250 mg. Increments of 250 mg. are added, usually at weekly intervals, to tolerance, or therapeutic effectiveness, up to daily doses not exceeding 2.0 Gm. A typical dosage schedule for the introduction of MYSOLINE (primidone) is as follows:

Adults and Children Over 8 Years of Age

1st Week 250 mg. daily at bedtime	*2nd Week* 250 mg. b.i.d.
3rd Week 250 mg. t.i.d.	*4th Week* 250 mg. q.i.d.

In children under 8 years of age, maintenance levels are established by a similar schedule, but at one-half the adult dosage. It is best to begin with 125 mg., with gradual weekly increases of 125 mg. a day, to a daily total usually between 500 mg. and 750 mg.



In patients already receiving other anticonvulsants: MYSOLINE should be gradually increased as dosage of the other drug(s) is maintained or gradually decreased. This regimen should be continued until satisfactory dosage level is achieved for combination, or the other medication is completely withdrawn. When therapy with this product alone is the objective, the transition should not be completed in less than two weeks.

MYSOLINE 50 mg. Tablet can be used to practical advantage when small fractional adjustments (upward or downward) may be required, as in the following circumstances:

- for initiation of combination therapy
- during "transfer" therapy
- for added protection in periods of stress or stressful situations that are likely to precipitate seizures (menstruation, allergic episodes, holidays, etc.)

HOW SUPPLIED: MYSOLINE *Tablets*—No. 430—Each tablet contains 250 mg. of primidone (scored), in bottles of 100 and 1,000. Also in unit dose package of 100. No. 431—Each tablet contains 50 mg. of primidone (scored), in bottles of 100 and 500. MYSOLINE *Suspension*—No. 3850—Each 5 cc. (teaspoonful) contains 250 mg. of primidone, in bottles of 8 fluid-ounces.

A Timely New Book from The Joint Information Service

This latest Joint Information Service field study provides a concise, comprehensive overview of the complex matter of the very young American child and his mental health, and then describes in intimate detail seven unique programs for pre-school children with problems—from North Hollywood's Dubnoff Center, emphasizing education as its primary therapeutic modality, to Baltimore's Martin Luther King, Jr. Parent-Child Center, serving two housing projects, served by Johns Hopkins, and largely governed by its own people. All different in treatment approach and philosophy, the programs described are uniform in their dedication to innovation in improving service to the emotionally disturbed very young child, and, equally, to the emotional well being of all young children.

This thoughtful and perceptive description of what has been created by some of the best informed, most experienced and thoughtful specialists in mental health services for very young children should be welcome to all involved in the mental health of children and a casebook for those dealing with child and family mental health.

An articulate exposition of the immense problems and encouraging accomplishments in a particularly difficult area of endeavor . . . . Beyond their concern with the manifestly ill child, the authors intriguingly explore what may be needed to enhance the mental good health of all young children . . . . A significant contribution.

James N. Sussex, M.D.
President, American Association of Psychiatric Services for Children

Put depression to rest

The h.s. schedule: provides symptomatic relief throughout the next day.

Because of its pharmacokinetic characteristics, Endep (amitriptyline HCl) Roche, provides the same clinical effect over a period of time when given as a single daily *h.s.* dose or as 1/3 the same dose given *t.i.d.*

Midnight

The h.s. schedule: helps put side effects in their place.

100 mg Endep *h.s.* can provide relief of depression-induced insomnia. Once asleep, the patients are also less likely to notice anticholinergic side effects—such as dry mouth—which reach a peak hours after the *h.s.* dose.

Because the sedative effect may impair patients' performance during daytime, warn patients not to drive or operate dangerous machinery until the sedative potential has been clearly established.

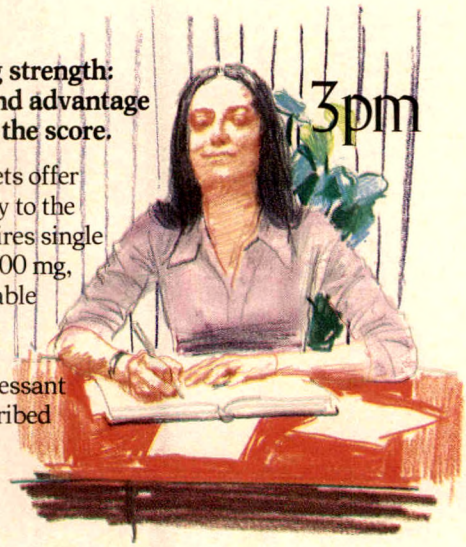
The h.s. schedule: helps maximize patient compliance.

According to one investigation, only 40% of patients comply with a *t.i.d* drug schedule whereas 93% of patients comply with a one-dose-a-day schedule.[1] An *h.s.* schedule of Endep (amitriptyline HCl), therefore, should help you maximize patient compliance which, in turn, helps ensure prompt recovery.

ROCHE

all day long

The 100-mg strength: early signs of progress.



Many depressed patients with insomnia and anorexia begin to show improvement during the first week of Endep (amitriptyline HCl) therapy. Patients with symptoms of "neurotic" depression usually improve during the first week, whereas those with "psychotic" depression usually do not improve until the third week of therapy. However, adequate response may require up to 30 days in both types.

8am

Noon

3pm

The 100-mg strength: the economy and advantage of knowing the score.

100-mg tablets offer potential economy to the patient who requires single doses of 50 mg, 100 mg, or 150 mg. Available as scored tablets, Endep is the only tricyclic antidepressant that can be prescribed in half doses.

The 100-mg strength: emphasis on individualization of dosage.

The introduction of the 100-mg scored tablet brings to 5 the number of Endep dosage strengths now available as scored tablets: 10 mg, 25 mg, 50 mg, 75 mg, and 100 mg.

7pm

with new 100mg Endep®

amitriptyline HCl/Roche

Before prescribing, please consult complete product information, a summary of which appears on the following page.

Endep®
amitriptyline HCl/Roche

10 mg | 25 mg | 50 mg | 75 mg | Just released 100 mg

The only tricyclic antidepressant with scored tablets

- By relieving underlying depression Endep (amitriptyline HCl), in responsive patients, lifts mood and relieves symptoms such as anorexia, loss of interest, inability to concentrate, decreased libido or GI disturbances, often within three or four weeks after starting therapy.
- Endep usually relieves accompanying sleep disturbances, particularly early in the treatment regimen.
- All five dosage strengths are scored for greater flexibility and convenience in titration.
- The *h.s.* dosage minimizes skipped doses, maximizes patient acceptance and compliance.
- Specifying Endep assures quality plus potential economy.

Important Considerations

'Should not be given concomitantly with an MAO inhibitor or within 2 weeks of its administration.

Patients should use caution in the performance of hazardous tasks such as operating machinery or driving a motor vehicle.

May enhance the effects of alcohol, barbiturates and other CNS depressants.

Not recommended for use during the acute recovery phase following myocardial infarction.

Patients with suicidal tendencies should not have easy access to large quantities of the drug.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: To relieve symptoms of depression (notably endogenous depressions) and depression accompanied by anxiety.

Contraindications: Known hypersensitivity. Do not use with monoamine oxidase (MAO) inhibitors or within at least 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Use not recommended during acute recovery phase after myocardial infarction.

Warnings: May block action of guanethidine or similar antihypertensives. Use with caution in patients with history of seizures, urinary retention, angle closure glaucoma, increased intraocular pressure. Closely supervise cardiovascular patients, hyperthyroid patients and those receiving thyroid medications. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, including amitriptyline HCl, especially in high doses. Myocardial infarction and stroke reported with use of this class of drugs.) May impair alertness; warn against hazardous occupations or driving a motor vehicle during therapy. Weigh possible benefits against hazards during pregnancy, the nursing period and in women of childbearing potential. Not recommended in children under 12.

Precautions: May exaggerate symptoms in schizophrenic and paranoid patients, or shift manic-depressives to manic stage; reduce dose or administer major tranquilizer concomitantly. Close supervision and careful dose adjustments required when given with anticholinergic or sympathomimetic agents. Exercise care in patients receiving large doses of ethchlorvynol; transient delirium reported with concomitant administration. May enhance effects of alcohol, barbiturates and other CNS depressants. Because of the possibility of suicide in depressed patients, do not permit easy access to large drug quantities in these patients. Because it may increase hazards of electroshock therapy, limit concomitant use to essential treatment. If possible, discontinue drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: This list includes a few adverse reactions not reported with this specific drug but requiring consideration because of similarities of tricyclic antidepressants. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, jaundice, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache and malaise. These are not indicative of addiction.

Dosage: Initiate at low levels; increase gradually, watching for signs of intolerance. As long as 30 days may elapse before adequate antidepressant effect develops; sedative effect may be noted earlier.

Initial Adult Dosage: Outpatients—25 mg *t.i.d.*; may be increased to 150 mg/day. Add increased drug to afternoon and/or bedtime doses. Alternate—50 to 100 mg *h.s.*, gradually increasing *h.s.* dose up to 150 mg/day. Hospitalized Patients—Up to 100 mg/day; increase gradually to 200 mg if necessary. A few patients may require 300 mg/day.

Adolescent and Elderly Patients: In general, 10 mg *t.i.d.* with 20 mg *h.s.* may be satisfactory for those who do not tolerate higher doses.

Maintenance Dosage: With symptomatic improvement, reduce dosage to lowest amount that gives relief, usually 25 mg *b.i.d.* to *q.i.d.*, or 10 mg *q.i.d.* Continue maintenance therapy 3 months or longer to avoid relapse.

Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. IV administration of 1 to 3 mg physostigmine salicylate reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestations and treatment.

Supplied: 10-mg, 25-mg, 50-mg, 75-mg and 100-mg scored tablets—bottles of 100 and 500; Tel-E-Dose® packages of 100; Prescription Paks of 60 (10 mg, 25 mg and 50 mg) or 30 (75 mg and 100 mg), available singly and in trays of 10.

Where The Action Is—

For more than a decade the general hospital psychiatric unit has been the principal locus of inpatient treatment. This latest Joint Information Service national survey brings up to date its earlier—and the original—study of this important component of the psychiatric scene. It reveals that the remarkable rate of growth held up, showing an increase of 50 percent in the number of units between 1963 and 1971, and an increase of 46 percent in the number of admissions. And it verifies that general hospital psychiatry has become increasingly comprehensive, with an impressively high level of outpatient service, emergency service, and even consultation to community agencies. Indeed, the general hospital accounts for several times as much service and activity as the widely heralded federally supported community mental health center.

This study also involves the private psychiatric hospitals, which have not changed much in number but are admitting about 10,000 more patients than in 1964—and they, too, are providing a remarkably comprehensive program.

It's your responsibility to be well-informed about these extraordinarily significant and vital pieces of American psychiatric service. You can do so by sending the order form below.

Basic tools of primitive psychiatry

Mankpo: Sceptres or staffs used by the Heviosso (lightning God) cult in medical ceremonies among the Ewe of Tongo and Fon of Dahomey. *Right,* staff with leopard's head, bared teeth and tongue (Ewe, Togo). *Left,* staff with ram's head—the sacred animal of the Heviosso—in the form of a serpent symbolizing the fire-spitting rainbow God of healing (Fon, Dahomey). From the collection of the Segy Gallery, New York City.

Basic tool of Western psychiatry

Thorazine®
(chlorpromazine, SK&F)

Tablets: 25 and 50 mg of the HCl

- 'Thorazine' controls psychotic symptoms
- Especially useful in agitated, violent or anxious schizophrenic patients
- Unsurpassed clinical experience
- 18 convenient dosage forms and strengths

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of manifestations of psychotic disorders. For control of the manifestations of manic-depressive illness (manic phase).

Probably effective: For the control of moderate to severe agitation, hyperactivity or aggressiveness in disturbed children.

Possibly effective: For control of excessive anxiety, tension and agitation as seen in neuroses.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose states, presence of large amounts of C.N.S. depressants, or bone marrow depression.

Warnings: Avoid using in patients hypersensitive (e.g., blood dyscrasia, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery) especially during the first few days' therapy. Avoid concomitant use with alcohol. May counteract antihypertensive effect of guanethidine and related compounds.

Use in pregnancy only when essential. There are reported instances of jaundice or prolonged extrapyramidal signs in newborn whose mothers had received chlorpromazine.

Precautions: Use cautiously in persons with cardiovascular, liver or chronic respiratory disease, or with acute respiratory infections. Due to cough reflex suppression, aspiration of vomitus is possible. May prolong or intensify the action of C.N.S. depressants, organophosphorus insecticides, heat, atropine and related drugs. (Reduce dosage of concomitant C.N.S. depressants.) Anticonvulsant action of barbiturates is not intensified. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Discontinue high-dose, long-term therapy gradually.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, cholestatic jaundice, agranulocytosis, eosinophilia, leukopenia, hemolytic anemia, thrombocytopenic purpura and pancytopenia; postural hypotension, tachycardia, fainting, dizziness and, occasionally, a shock-like condition; reversal of epinephrine effects; EKG changes have been reported, but relationship to myocardial damage is not confirmed; neuromuscular (extrapyramidal) reactions; pseudo-parkinsonism, motor restlessness, dystonias, persistent tardive dyskinesia, hyperreflexia in the newborn; psychotic symptoms, catatonic-like states, cerebral edema; convulsive seizures; abnormality of the cerebrospinal fluid proteins; urticarial reactions and photosensitivity, exfoliative dermatitis, contact dermatitis; lactation and breast engorgement (in females on large doses), false positive pregnancy tests, amenorrhea, gynecomastia; hyperglycemia, hypoglycemia, glycosuria; dry mouth, nasal congestion, constipation, adynamic ileus, urinary retention, miosis, mydriasis; after prolonged substantial doses, skin pigmentation, epithelial keratopathy, lenticular and corneal deposits and pigmentary retinopathy, visual impairment; mild fever (after large I.M. dosage); hyperpyrexia; increased appetite and weight; a systemic lupus erythematosus-like syndrome; peripheral edema.

NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 10 mg., 25 mg., 50 mg., 100 mg. and 200 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only). Spansule® capsules, 30 mg., 75 mg., 150 mg., 200 mg. and 300 mg., in bottles of 50; in Single Unit Packages of 100 (intended for institutional use only). Injection, 25 mg./ml.; Syrup, 10 mg./5 ml.; Suppositories, 25 mg. and 100 mg.; Concentrate (intended for institutional use only), 30 mg./ml. and 100 mg./ml.

For effective management of schizophrenic symptoms.

The schools don't like to get involved with medication for MBD – and now they don't have to

Importance of Cylert (pemoline) single daily dosage to the child, the parents and the teacher

For the child		For the adults
No drug in child's possession while at school	⟷	Control of medication remains with parents
Avoids situation in which child is repeatedly singled out as being "different"	⟷	Obviates need for teacher or nurse to supervise taking of mid-day doses
Helps prevent possible variations in effect caused by missed, forgotten or delayed doses	⟷	Helps assure that the prescribed dosage is being given each day

Cylert offers these benefits in a treatment program for MBD

- Single daily dose administration
- Minimal cardiovascular effects
- Mean dosage in long-term studies remained remarkably constant
- Can be taken with breakfast

Cylert® (pemoline) CIV

dosage is once-a-day, given to the child at home by the parent

Cylert, alone among CNS stimulants used to treat MBD, is inherently long-acting, permitting once-daily dosage

Dosage and administration

Cylert is given as a single oral dose each morning.

The recommended starting dose is 37.5 mg. per day. This daily dosage should be gradually increased at one-week intervals using increments of 18.75 mg. until the desired clinical response is obtained.

The mean daily effective dose ranges from 56.25 to 75 mg. per day. The maximum recommended daily dose of Cylert is 112.5 mg.

Using the recommended schedule of dose titration, significant benefits may not be seen until the third or fourth week of drug therapy. Side effects may be seen prior to optimum clinical results.

When not to use Cylert

Cylert should not be used for (and will not be effective in) simple cases of overactivity in school age children.

Neither should it be used in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

The physician should rely on a complete history of the child and a thorough description of symptoms from both parents and teacher before postulating a diagnosis of MBD.

Please see next page for Prescribing Information

60831-44

Cylert®
(pemoline) CIV

Prescribing Information

Description: Cylert (pemoline) is a white, tasteless, odorless powder which is relatively insoluble (less than 1 mg/ml) in water, chloroform, ether, acetone, and benzene. In 95% ethyl alcohol, the solubility of pemoline is 2.2 mg/ml.

Actions: Cylert (pemoline) is a central nervous system stimulant. The pharmacologic activity of pemoline is similar to that of other known stimulants but with minimal sympathomimetic effects. Pemoline is structurally dissimilar from the amphetamines and methylphenidate. Although the exact mode of pharmacodynamic action is undetermined in man, pemoline has been reported to increase the rate of synthesis of dopamine in rat brain.

In human subjects, Cylert produces peak blood levels within 2-4 hours. The serum half-life is approximately 12 hours. Multiple dose studies in adults at several dose levels indicate that serum levels plateau in approximately three days. Cylert and its metabolites are primarily excreted by the kidneys with approximately 75% of an oral dose appearing in the urine within a 24-hour period. Approximately 43% of pemoline is excreted unchanged. Metabolites include pemoline dione, conjugated pemoline and mandelic acid.

Cylert (pemoline) has a gradual onset of action in children with minimal brain dysfunction. Using the recommended schedule of dosage titration, significant clinical benefit may not be evident until the third or fourth week of drug administration.

Indications: MINIMAL BRAIN DYSFUNCTION IN CHILDREN—as adjunctive therapy to other remedial measures (psychological, educational, social).

Special Diagnostic Considerations: Specific etiology of minimal brain dysfunction (MBD) is unknown, and there is no single diagnostic test. Adequate diagnosis includes the use not only of medical but of psychological, educational, and social resources.

Characteristics commonly reported include: A chronic history of moderate to severe hyperactivity, short attention span, distractibility, emotional lability, and impulsivity. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with MBD. In the primary therapy of MBD, appropriate educational placement is essential and psychosocial intervention is generally necessary. When these measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

Contraindication: Cylert (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See PRECAUTIONS)

Warnings: Cylert is not recommended for children under six years of age since safety and efficacy in this age group have not yet been established.

Since Cylert (pemoline) and its metabolites are excreted primarily by the kidneys, caution should be observed in administering the drug to children with significantly impaired renal function.

Sufficient data on safety and efficacy of Cylert administration for periods beyond two years duration in children with minimal brain dysfunction are not yet available. Although a definite causal relationship has not been established, some temporary suppression of predicted growth pattern(i.e., weight and/or height) has been reported with the long-term use of stimulants in children. Therefore, patients requiring long-term therapy should be carefully monitored.

Drug Interactions: Interactions between Cylert and other drugs have not been studied in humans. As with most other drugs, concurrent administration with other agents, especially drugs with central nervous system activity, should be carefully monitored.

Usage in Pregnancy: Safety for use in pregnancy has not been established. Standard studies of fertility, teratology and reproduction were conducted in rats and rabbits. Daily oral doses of pemoline of 18.75 and 37.5 mg/kg beginning at conception produced no abnormalities in the fetuses and did not affect viability at birth. Further studies using similar dose levels with drug administration beginning 14 days before conception demonstrated an increased incidence of stillbirths in these animals.

Drug Dependence: Studies of the drug abuse potential of Cylert (pemoline) in primates have not demonstrated a potential for self-administration. However, the pharmacologic similarities between Cylert and other CNS stimulants with known abuse liability suggest that drug dependence of the stimulant type might occur. There have been isolated reports of transient psychotic symptoms in adults following long-term misuse of pemoline taken orally in excessive quantities. Therefore, caution should be observed in emotionally unstable patients considered to have a psychological potential for drug dependence.

Precautions: Delayed hypersensitivity reactions involving the liver have been reported in 1-2% of the patients receiving Cylert usually after several months of therapy. No clinical symptomatology has been observed, but mild to moderate increases in transaminase (SGOT and SGPT) levels have occurred in these cases. These effects appear to be completely reversible when drug treatment is discontinued. Transaminase levels should be determined periodically during therapy with Cylert to detect any such reactions.

Adverse Reactions: The most frequently reported adverse reaction with Cylert is insomnia. Insomnia has been observed prior to optimum therapeutic response and in the majority of cases was transient in nature or responded to dosage reduction. Anorexia with weight loss during the first few weeks of therapy has also been reported. With continuing therapy, a return to a normal weight curve usually occurred within three to six months. Other adverse reactions reported include stomachache, skin rash, irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations. Mild adverse reactions appearing early in treatment often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage reduction or discontinuation should be considered.

Dosage and Administration: Cylert (pemoline) is administered as a single oral dose each morning. The recommended starting dose is 37.5 mg per day. This daily dosage should be gradually increased at one week intervals using increments of 18.75 mg until the desired clinical response is obtained. The mean daily effective dose ranges from 56.25 to 75 mg per day. The maximum recommended daily dose of pemoline is 112.5 mg.

Clinical improvement with Cylert is gradual. Using the recommended schedule of dosage titration, significant benefit may not be evident until the third or fourth week of drug administration. Drug administration should be interrupted occasionally to determine if behavioral symptoms sufficient to require continuing therapy recur.

Overdosage: Cylert overdosage has been reported to produce symptoms of tachycardia, hallucinations, agitation, or restlessness. The treatment of acute massive overdosage with pemoline is essentially the same as that for overdosage with any drug having CNS stimulatory effects. Management is largely symptomatic and may include induction of emesis, gastric lavage or other measures as appropriate.

How Supplied: Cylert (pemoline) is supplied as monogrammed, grooved tablets in three dosage strengths:

18.75 mg. tablets (yellow-colored) in bottles of 100 (**NDC** 0074-6025-13)

37.5 mg. tablets (orange-colored) in bottles of 100 (**NDC** 0074-6057-13)

75 mg. tablets (tan-colored) in bottles of 100 (**NDC** 0074-6073-13)

Out of touch

but not beyond reach...

Help restore reality

Trilafon®

brand of perphenazine, NF

for management of disturbed behavior in schizophrenic and manic states

- low dose, high potency phenothiazine useful for inpatient and outpatient treatment
- helps orient psychiatric patients to their surroundings
- effective with minimal sedation, usually produces little lethargy or drowsiness

Versatile Dosage	
Injection	5 mg/ml, 1 ml ampul
Concentrate	16 mg/5 ml, 120 ml bottle
Tablets	2,4,8,16 mg
REPETABS® Tablets 8 mg brand of repeat-action tablets	

Please see next page for prescribing information.

Trilafon®
brand of perphenazine, NF

For management of schizophrenic and manic disorders in psychiatric hospitals, mental health clinics, and with outpatient treatment

TABLETS
for maintenance or control of patients in hospital or home

BENEFITS

- generally improve cooperation and communication
- decrease need for custodial care, hasten discharge

CONCENTRATE
for maintenance or control of uncooperative in-hospital patients

- easily mixes with most liquids
- ensures easy, steady, certain administration

INJECTION
for emergency control of uncooperative in-hospital patients

- usually takes effect in 10 minutes
- average duration of effect is 6 hours

TRILAFON® Tablets
brand of perphenazine, NF

REPETABS® Tablets
Concentrate
Injection

CONTRAINDICATIONS TRILAFON is contraindicated in drug-associated central nervous system depression (barbiturates, alcohol, narcotics, analgesics, antihistamines). Perphenazine is contraindicated in the presence of existing blood dyscrasias, bone marrow depression and pre-existing liver damage, and in patients who are hypersensitive to perphenazine.

TRILAFON **Injection** should not be given to patients in coma or severely depressed states.

WARNINGS **Dosage in pregnancy:** Perphenazine should only be given to pregnant patients when, in the judgment of the physician, the potential benefits outweigh the possible risks.

Perphenazine can lower the convulsive threshold in susceptible individuals; it should be used with caution in patients with convulsive disorders. If the patient is being treated with an anticonvulsant agent, increased dosage of that agent may be required when perphenazine is used concomitantly.

Perphenazine should be used with caution in patients with psychic depression.

Perphenazine is not recommended for children under 12 years of age.

Perphenazine may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks, such as driving a car or operating machinery.

PRECAUTIONS As with any potent medication, patients receiving perphenazine should be under medical supervision, particularly if they are receiving high doses. Patients who have had any severe reaction to phenothiazines or to imipramine should be treated cautiously, under close medical supervision.

Although the following adverse reactions have not been reported in patients treated with perphenazine, the possibility that they might occur with TRILAFON should be considered: blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, eosinophilia); liver damage (biliary stasis); narrowing of the visual fields; pigmentation of the retina, cornea, or lens; cerebral edema; polyphagia; photophobia; hyperpyrexia.

If hypotension develops, levarterenol (norepinephrine) can be used, but not epinephrine, because epinephrine's action is blocked and partly reversed by perphenazine. Severe, acute hypotension has occurred with the use of phenothiazines and is of particular concern in patients with mitral insufficiency or pheochromocytoma.

A significant rise in body temperature may indicate an idiosyncratic reaction to perphenazine; treatment with perphenazine should be stopped if this occurs.

The antiemetic effect of perphenazine can obscure signs of toxicity due to overdosage of other drugs, or mask the symptoms of disease (eg, brain tumor or intestinal obstruction).

Contact dermatitis has been reported with a perphenazine solution; therefore, contact of hands or clothing by those handling perphenazine solutions should be avoided.

POTENTIATION Since phenothiazines can potentiate the central-nervous-system-depressant actions of opiates, antihistamines, barbiturates, and alcohol, less than the usual dosage of these agents is required when they are administered concomitantly with TRILAFON. Patients should be cautioned that their response to alcohol may be increased while they are being treated with TRILAFON.

Phenothiazines also potentiate the effects of atropine, heat, and phosphorus insecticides, and should be used with caution in persons exposed to these agents.

ADVERSE REACTIONS *Extrapyramidal reactions:* dystonia including protrusion, discoloration, aching and rounding of the tongue; tonic spasm of the masticatory muscles, tight feeling in the throat, slurred speech, dysphagia, oculogyric crisis, trismus, torticollis, retrocollis, muscle weakness, and aching and numbness of the limbs; akathisia; motor restlessness; dyskinesia, parkinsonism; hyperreflexia; and ataxia. The incidence and severity of these reactions usually increase with increased dosage, but have occurred in some patients receiving low dosage. Reduction in dosage or treatment with an antispasmodic agent will usually control extrapyramidal reactions. In some instances, however, these reactions may persist after discontinuation of treatment with perphenazine.

Persistent tardive dyskinesia: As with all antipsychotic agents, tardive dyskinesia may appear in some patients on long-term therapy or may appear after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (eg, protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities. There is no known effective treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been reported that fine, vermicular movements of the tongue may be an early sign of the syndrome, and if the medication is stopped at that time the syndrome may not develop.

Allergic reactions: erythema, pruritus, urticaria, eczema, anaphylactoid reactions, and local and generalized edema. In extremely rare instances, individual idiosyncrasy or hypersensitivity to phenothiazines has resulted in cerebral edema, circulatory collapse, and death. Photosensitization, asthma, and exfoliative dermatitis have also occurred in patients treated with phenothiazines.

Autonomic reactions: blurred vision, dry mouth or salivation, nasal congestion, nausea, vomiting, hypertension, tachycardia, hypotension, anorexia, urinary frequency or incontinence, and constipation. Significant autonomic effects have been infrequent in patients receiving less than 24 mg. perphenazine daily.

Other reactions: endocrine disturbances (lactation, gynecomastia, galactorrhea, disturbances in the menstrual cycle), headaches, mild insomnia, altered cerebrospinal fluid proteins, ECG abnormalities, reactivation of psychosis, paradoxical excitement, paranoid-like reactions, catatonia, and systemic lupus erythematosus-like syndrome. Hypnotic effects appear to be minimal, particularly in patients who are permitted to remain active. The following adverse reactions, though rare, have also been reported to be associated with perphenazine treatment: agranulocytosis; jaundice; hyperpigmentation of the skin; grand mal convulsions; failure of ejaculation; hyperglycemia.

Side effects with intramuscular TRILAFON **Injection** have been infrequent and transient. Dizziness or significant hypotension after treatment with TRILAFON (perphenazine) **Injection** is a rare occurrence.

SWW-5320

a valuable link to the resources of the American Psychiatric Association

for institutions and agencies concerned with the care of the mentally disabled

Enrollment in the Hospital & Community Psychiatry Service brings multiple copies of *Hospital & Community Psychiatry* into member agencies every month, keeping staff up to date on developments and issues in the mental health field, offering new ideas and fresh perspectives, and serving as a useful resource in staff development and training programs.

Hospital & Community Psychiatry is just one of the benefits of membership in the H&CP Service. Others include a film library containing more than a hundred films specially chosen for their usefulness in staff development and community education programs; supplementary mailings of important books, reports, articles, or other material of special interest to administrators or clinicians; reduced registration fees at the annual fall Institute on Hospital & Community Psychiatry; and, on request, information and consultation from the professional staff of the American Psychiatric Association. The H&CP Service also sponsors the annual Achievement Awards competition, which gives special recognition to outstanding programs for the mentally ill and mentally retarded.

Please send me information about membership in the Hospital & Community Psychiatry Service.

LIBRIUM®
(chlordiazepoxide HCl)
5 mg, 10 mg, 25 mg capsules

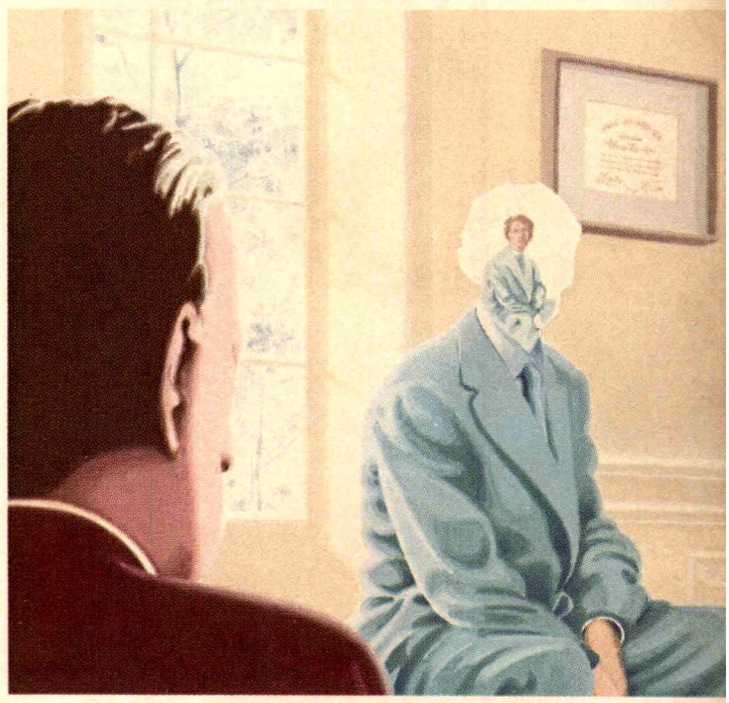
Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported. Use of any drug in pregnancy, lactation, or in women of childbearing age requires that its potential benefits be weighed against its possible hazards.

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.



Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Supplied: Librium® Capsules containing 5 mg, 10 mg, or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.

ROCHE Roche Laboratories Division of Hoffmann-La Roche Inc. Nutley, New Jersey 07110

EXPERIENCE. CONSISTENT EFFICACY IN REDUCING "ANXIETY BLOCK."

During the entry phase of psychotherapy, heightened levels of obstructive anxiety are often encountered. At such times, the dependable antianxiety action of Librium can effectively facilitate verbal communication, helping to foster a more productive relationship between patient and physician — usually without impairing mental acuity.

A consistent pattern of patient response

As treatment progresses and disturbing psychologic material is brought to the surface, anxiety may again rise sharply, creating patient resistance to further exploration. During this probe phase, adjunctive Librium has demonstrated its ability to relieve excessive anxiety and help the patient handle his emerging insights — especially as he seeks to apply those hard-won insights in his daily life.

A highly favorable benefits-to-risk ratio

The most common side effects of Librium are dose-related and thus largely avoidable. There appears to be a low incidence of drug dependence and tolerance. Librium rarely has been reported to have an adverse effect on the cardiovascular or respiratory system and is used concomitantly with many primary medications.

As with all CNS-acting agents, patients taking Librium should be cautioned against hazardous activities requiring complete mental alertness, and against combined effects with alcohol and other CNS depressants. Once anxiety has been reduced to manageable levels, Librium should be discontinued.

The George Washington University Medical Center is seeking a Chairperson of the Department of Psychiatry and Behavioral Science. The Department has a full time faculty of 10 persons, and a large voluntary faculty throughout the metropolitan Washington area. Resources include a 33 bed unit within the University Hospital, an ambulatory facility caring for 10,000 visits per year, a substantial research program centered on family therapy and drug and alcohol abuse, a training program to include 6 residents per year, and extensive input into each of the 4 years of the medical school curriculum. Capacity to develop liaison with Washington psychiatric community and mental health resources is a Medical Center priority. Applicant should have significant experience in administration in a medical school or related programs. Write Thomas E. Piemme, M.D., Chairman, Search Committee, 1229 25th Street, N.W., Washington, D.C. 20037. An equal opportunity employer.

Psychiatrists

We are a large progressive community based JCAH accredited and medical school affiliated psychiatric facility undergoing accelerated expansion of services. Present openings for INPATIENT AND OUTPATIENT STAFF PSYCHIATRISTS require licensure in any state or in Canada by examination and completion of approved psychiatric residency program. We offer a starting salary commensurate with your background, comprehensive fringe benefits and an innovative environment conducive to ongoing professional development.

Equal Opportunity Employer.

IMMEDIATE OPENINGS FOR PSYCHIATRISTS at Richard H. HUTCHINGS PSYCHIATRIC CENTER

- Opportunities for innovation, research and teaching in Community psychiatry
- Major affiliation with SUNY College of Medicine at Syracuse
- Initial appointment is as director of a 12-24 bed multi disciplinary treatment team
- Opportunities for advancement and additional responsibility as Center expands
- Salary commensurate with training and experience
- Extensive benefits

For more information contact:

NEW ORAL CONCENTRATE

Loxitane® C

LOXAPINE HYDROCHLORIDE

Lederle

25 mg base/ml* In bottles of 4 fl. oz.

Effectiveness – the only clue that it's there

DESCRIPTION

*Each ml contains the equivalent of 25 mg loxapine base as the HCl.

LOXITANE *loxapine*, a dibenzoxazepine compound represents a new subclass of tricyclic antipsychotic agent, chemically distinct from the thioxanthenes, butyrophenones, and phenothiazines. Chemically, it is 2-chloro-11-(4-methyl-1-piperazinyl)dibenz[b,f][1,4]oxazepine. It is present in the oral concentrate primarily as the HCl.

ACTIONS

Pharmacologically, loxapine is a tranquilizer for which the exact mode of action has not been established. However, changes in the level of excitability of subcortical inhibitory areas have been observed in several animal species in association with such manifestations of tranquilization as calming effects and suppression of aggressive behavior.

In normal human volunteers, signs of sedation were seen within 20 to 30 minutes after administration, were most pronounced within 1 1/2 to 3 hours, and lasted through 12 hours. Similar timing of primary pharmacologic effects was seen in animals.

Absorption of loxapine following oral or parenteral administration is virtually complete. The drug is removed rapidly from the plasma and distributed in tissues. Animal studies suggest an initial preferential distribution in lungs, brain, spleen, heart, and kidney. Loxapine is metabolized extensively and is excreted mainly in the first 24 hours. Metabolites are excreted in the urine in the form of conjugates and in the feces unconjugated.

INDICATIONS

LOXITANE C *loxapine hydrochloride* is indicated for the manifestations of schizophrenia.

LOXITANE has not been shown effective in the management of behavioral complications in patients with mental retardation.

CONTRAINDICATIONS

LOXITANE is contraindicated in comatose or severe drug-induced depressed states (alcohol, barbiturates, narcotics, etc.)

LOXITANE is contraindicated in individuals with known hypersensitivity to the drug.

WARNINGS

Usage in Pregnancy: Safe use of LOXITANE C *loxapine hydrochloride* during pregnancy or lactation has not been established; therefore, its use in pregnancy, in nursing mothers, or in women of childbearing potential requires that the benefits of treatment be weighed against the possible risks to mother and child. No embryotoxicity or teratology was observed in studies in rats, rabbits or dogs, although with the exception of one rabbit study, the highest dosage was only two times the maximum recommended human dose and in some studies they were below this dose. Perinatal studies have shown renal papillary abnormalities in offspring of rats treated from mid-pregnancy with doses of 0.6 and 1.8 mg/kg, doses which approximate the usual human dose but which are considerably below the maximum recommended human dose.

Usage in Children: Studies have not been performed in children; therefore this drug is not recommended for use in children below the age of 16.

LOXITANE C *loxapine hydrochloride*, like other tranquilizers, may impair mental and/or physical abilities, especially during the first few days of therapy. Therefore, ambulatory patients should be warned about activities requiring alertness (e.g, operating vehicles or machinery), and about concomitant use of alcohol and other CNS depressants.

PRECAUTIONS

LOXITANE should be used with extreme caution in patients with a history of convulsive disorders since it lowers the convulsive threshold. Seizures have been reported in epileptic patients receiving LOXITANE at antipsychotic dose levels, and may occur even with maintenance of routine anticonvulsant drug therapy.

Tasteless in orange, grapefruit and pineapple juices

Highly acceptable to patients who prefer medication in fruit juices, and a logical alternative to tablets or capsules when good patient management depends on uninterrupted treatment. LOXITANE C Oral Concentrate is as easy to take as the fruit juice in which it may be administered.

Same efficacy as LOXITANE Capsules

Efficacy that speaks for itself with substantial reduction in the symptoms of schizophrenia.

Same favorable side effects profile as with LOXITANE Capsules[1]

In 31 studies involving 469 schizophrenic patients, certain favorable trends were exhibited in the LOXITANE side effects profile; these require further tests and broader clinical experience for confirmation.[1]

Same daily dosage schedule as with LOXITANE Capsules

The dropper is calibrated to conform to usual dosage requirements.

Loxapine has an antiemetic effect in animals. Since this effect may also occur in man, loxapine may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

LOXITANE should be used with caution in patients with cardiovascular disease. Increased pulse rates have been reported in the majority of patients receiving antipsychotic doses; transient hypotension has been reported. In the presence of severe hypotension requiring vasopressor therapy, the preferred drugs may be norepinephrine or angiotensin. Usual doses of epinephrine may be ineffective because of inhibition of its vasopressor effect by loxapine.

The possibility of ocular toxicity from loxapine cannot be excluded at this time. Therefore, careful observation should be made for pigmentary retinopathy and lenticular pigmentation since these have been observed in some patients receiving certain other antipsychotic drugs for prolonged periods.

Because of possible anticholinergic action, the drug should be used cautiously in patients with glaucoma or a tendency to urinary retention, particularly with concomitant administration of anticholinergic-type antiparkinson medication.

ADVERSE REACTIONS

CNS Effects: Manifestations of adverse effects on the central nervous system, other than extrapyramidal effects, have been seen infrequently. Drowsiness, usually mild, may occur at the beginning of therapy or when dosage is increased.

It usually subsides with continued LOXITANE therapy. The incidence of sedation has been less than that of certain aliphatic phenothiazines and slightly more than the piperazine phenothiazines. Dizziness, faintness, staggering gait, muscle twitching, weakness, and confusional states have been reported.

Extrapyramidal Reactions—Neuromuscular (extrapyramidal) reactions during the administration of LOXITANE C *loxapine hydrochloride* have been reported frequently, often during the first few days of treatment. In most patients, these reactions involved Parkinson-like symptoms such as tremor, rigidity, excessive salivation, and masked facies. Akathisia (motor restlessness) also has been reported relatively frequently. These symptoms are usually not severe and can be controlled by reduction of LOXITANE dosage or by administration of antiparkinson drugs in usual dosage. Dystonic and dyskinetic reactions have occurred less frequently, but may be more severe. Dystonias include spasms of muscles of the neck and face, tongue protrusion, and oculogyric movement. Dyskinetic reaction has been described in the form of choreo-athetoid movements. These reactions sometimes require reduction or temporary withdrawal of LOXITANE dosage in addition to appropriate counteractive drugs.

Persistent Tardive Dyskinesia—As with all antipsychotic agents, tardive dyskinesia may appear in some patients on long-term therapy or may appear after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movement of the tongue, face, mouth, or jaw (eg, protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia; antiparkinson agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been suggested that fine vermicular movements of the tongue may be an early sign of the syndrome, and if the medication is stopped at that time the syndrome may not develop.

Cardiovascular Effects: Tachycardia, hypotension, hypertension, lightheadedness, and syncope have been reported.

A few cases of ECG changes similar to those seen with phenothiazines have been reported. It is not known whether these were related to loxapine administration.

Skin: Dermatitis, edema (puffiness of face), pruritus, and seborrhea have been reported with loxapine. The possibility of photosensivitity and/or phototoxicity occurring has not been excluded; skin rashes of uncertain etiology have been observed in a few patients during hot summer months.

Endocrine Effects: No endocrine abnormalities have been reported.

Anticholinergic Effects: Dry mouth, nasal congestion, constipation, and blurred vision have occurred; these are more likely to occur with concomitant use of antiparkinson agents.

Other Adverse Reactions: Nausea, vomiting, weight gain, weight loss, dyspnea, ptosis, hyperpyrexia, flushed facies, headache, paresthesia, and polydipsia have been reported in some patients.

DOSAGE AND ADMINISTRATION

LOXITANE C *loxapine hydrochloride* is administered orally usually in divided doses two to four times a day. Daily dosage (in terms of base equivalents) should be adjusted to the individual patient's needs as assessed by the severity of symptoms and previous history of response to antipsychotic drugs. Initial dosage of 10 mg twice daily is recommended, although in severely disturbed patients initial dosage up to a total of 50 mg daily may be desirable. Dosage should then be increased fairly rapidly over the first seven to ten days until there is effective control of psychotic symptoms. The usual therapeutic and maintenance range is 60 mg to 100 mg daily. However, as with other antipsychotic drugs, some patients respond to lower dosage and others require higher dosage for optimal benefit. Daily dosage higher than 250 mg is not recommended. For maintenance therapy, dosage should be reduced to the lowest level compatible with symptom control; many patients have been maintained satisfactorily at dosages in the range of 20 mg to 60 mg daily.

LOXITANE C Oral Concentrate should be mixed with orange or grapefruit juice shortly before administration.

Use only the enclosed calibrated (10 mg, 15 mg, 20 mg, 25 mg) dropper for dosage.

HOW SUPPLIED

LOXITANE C *loxapine hydrochloride* is supplied in bottles of 4 fl. oz. (120 ml) with calibrated dropper. Each ml contains the equivalent of 25 mg loxapine base as the HCl. Rev 4/76

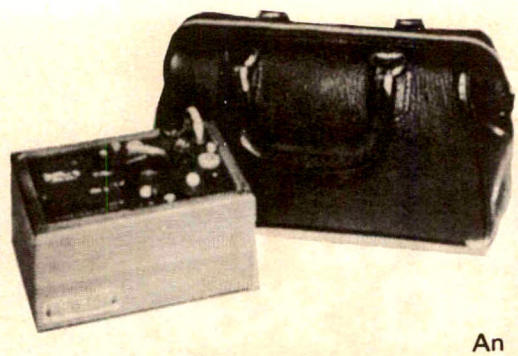
MORE THAN 30 YEARS...

have proven the dependability and effectiveness of REITER ELECTROSTIMULATORS in psychiatry! Research and constant improvements to meet the standards of improved techniques have kept Reiter instruments

THE WORLD'S MOST ACCEPTED ELECTROSTIMULATORS

The Two Popular Models— **PORTABLE FOR OFFICE AND CLINIC**



The Reiter MODEL SOS—THE ONE INSTRUMENT FOR ALL ESTABLISHED TECHNIQUES, provides the fullest range of safest therapies. For painless, gentle stimulation of the conscious patient to relieve anxiety, depression, etc. Maximum safety, no additives—patient conscious and cooperating with therapy.

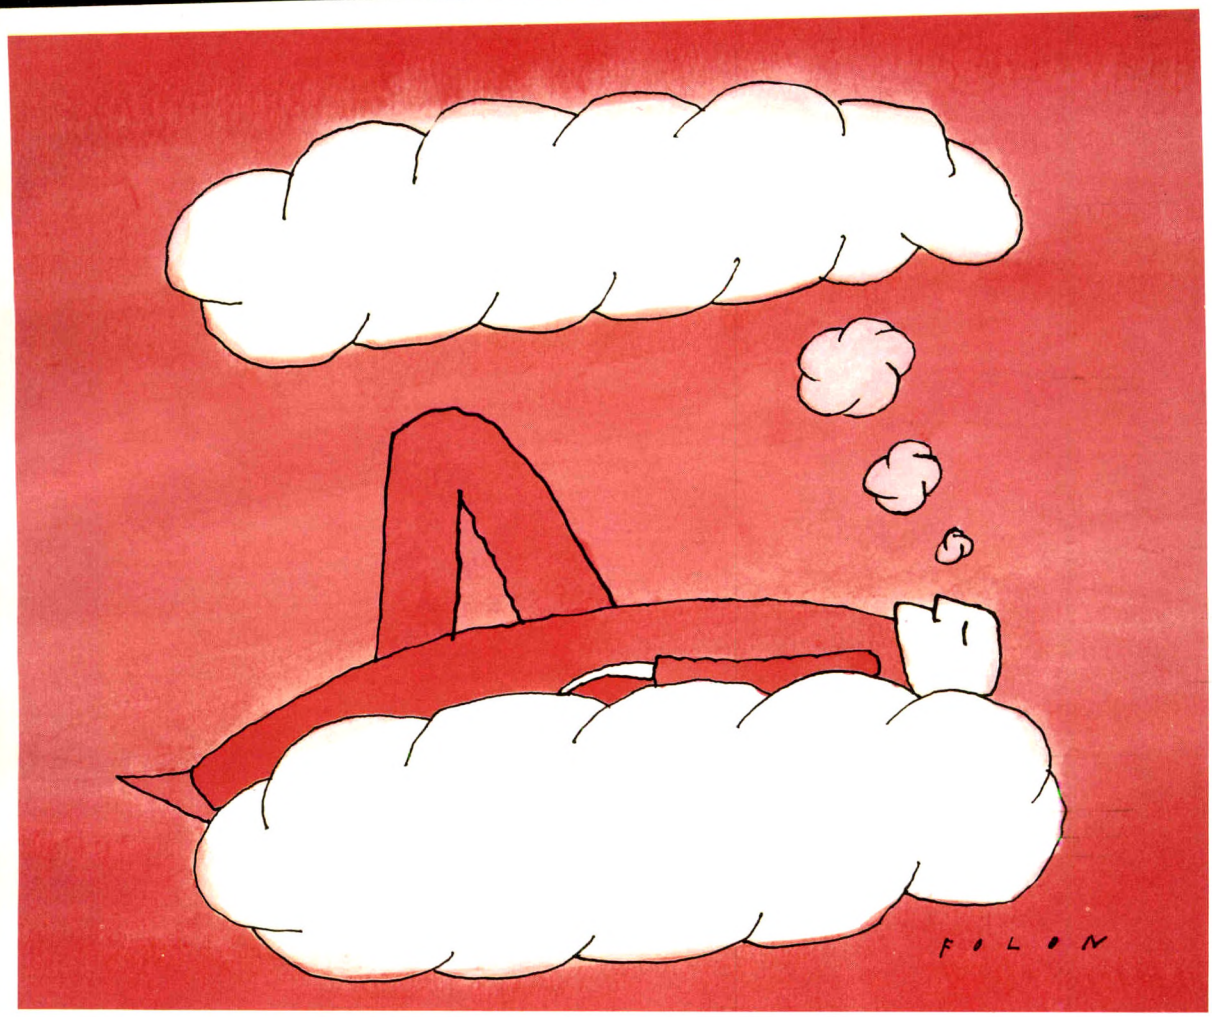
The SOS has also been used universally for Convulsive Therapy, Non-Convulsive Therapies, Electro-Sleep Therapy, Focal Treatment, Mono-Polar Treatment, Barbiturate Coma (and other respiratory problems), Mild Sedac, Deep Sedac Therapy, Pre-Convulsive Sedac, Post-Convulsive Sedac, Neurological Conditions, and Measurement Procedures.

Available with this redesigned model, on request, the following special-purpose electrodes —a Multi-Polar "Collar" type for Sleep Therapy, a "Horseshoe" assembly for quicker, surer application with one hand at last moment before ECT treatment, and a "Unilateral" type assembly.

Also built-in on request, an **automatic switch** for quicker build up to therapeutic ranges of Sedac.

SPECIAL MODEL SOS available without unidirectional convulsive current.

The Reiter Compact MOL-AC II—The smallest, lightest, least expensive and most reliable, clinically proven A.C. shock therapy instrument. Less confusion than from similar A.C. equipment. Now available with redesigned, improved panel. This compact instrument is only 3 x 5 inches, weighs but 3 lbs., yet provides full positive control of glisando effect over entire voltage range, as well as a positive manual control of time. There are NO complicated settings of dials, NO waiting for resetting of time devices, no warm-up delays.



An officially approved, extremely durable instrument which has earned world-wide professional acceptance, the MOL-AC II is economically priced with a fine, genuine leather physician's bag included.

Other Models Still Available: The CW47, original therapeutic cerebral stimulator with only 3 of the 9 treatment current selections available on Model SOS.

Overview: Research on the Psychology of Women. II. Women in Families, Work, and Psychotherapy
by Anne M. Seiden

OFFICIAL JOURNAL OF THE
AMERICAN PSYCHIATRIC ASSOCIATION

Basic tools of primitive psychiatry

Mankpo: Sceptres or staffs used by the Heviosso (lightning God) cult in medical ceremonies among the Ewe of Tongo and Fon of Dahomey. *Right,* staff with leopard's head, bared teeth and tongue (Ewe, Togo). *Left,* staff with ram's head—the sacred animal of the Heviosso—in the form of a serpent symbolizing the fire-spitting rainbow God of healing (Fon, Dahomey). From the collection of the Segy Gallery, New York City.

Basic tool of Western psychiatry

Thorazine®
(chlorpromazine, SK&F)

UNIVERSITY OF ILLINOIS MEDICINE LIBRARY

Tablets: 25 and 50 mg of the HCl

- 'Thorazine' controls psychotic symptoms
- Especially useful in agitated, violent or anxious schizophrenic patients
- Unsurpassed clinical experience
- 18 convenient dosage forms and strengths

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of manifestations of psychotic disorders. For control of the manifestations of manic-depressive illness (manic phase).

Probably effective: For the control of moderate to severe agitation, hyperactivity or aggressiveness in disturbed children.

Possibly effective: For control of excessive anxiety, tension and agitation as seen in neuroses.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose states, presence of large amounts of C.N.S. depressants, or bone marrow depression.

Warnings: Avoid using in patients hypersensitive (e.g., blood dyscrasia, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery) especially during the first few days' therapy. Avoid concomitant use with alcohol. May counteract antihypertensive effect of guanethidine and related compounds.

Use in pregnancy only when essential. There are reported instances of jaundice or prolonged extrapyramidal signs in newborn whose mothers had received chlorpromazine.

Precautions: Use cautiously in persons with cardiovascular, liver or chronic respiratory disease, or with acute respiratory infections. Due to cough reflex suppression, aspiration of vomitus is possible. May prolong or intensify the action of C.N.S. depressants, organophosphorus insecticides, heat, atropine and related drugs. (Reduce dosage of concomitant C.N.S. depressants.) Anticonvulsant action of barbiturates is not intensified. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Discontinue high-dose, long-term therapy gradually.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, cholestatic jaundice, agranulocytosis, eosinophilia, leukopenia, hemolytic anemia, thrombocytopenic purpura and pancytopenia; postural hypotension, tachycardia, fainting, dizziness and, occasionally, a shock-like condition; reversal of epinephrine effects; EKG changes have been reported, but relationship to myocardial damage is not confirmed; neuromuscular (extrapyramidal) reactions; pseudo-parkinsonism, motor restlessness, dystonias, persistent tardive dyskinesia, hyperreflexia in the newborn; psychotic symptoms, catatonic-like states, cerebral edema; convulsive seizures; abnormality of the cerebrospinal fluid proteins; urticarial reactions and photosensitivity, exfoliative dermatitis, contact dermatitis; lactation and breast engorgement (in females on large doses), false positive pregnancy tests, amenorrhea, gynecomastia; hyperglycemia, hypoglycemia, glycosuria; dry mouth, nasal congestion, constipation, adynamic ileus, urinary retention, miosis, mydriasis; after prolonged substantial doses, skin pigmentation, epithelial keratopathy, lenticular and corneal deposits and pigmentary retinopathy, visual impairment; mild fever (after large I.M. dosage); hyperpyrexia; increased appetite and weight; a systemic lupus erythematosus-like syndrome; peripheral edema.

NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 10 mg., 25 mg., 50 mg., 100 mg. and 200 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only). Spansule® capsules, 30 mg., 75 mg., 150 mg., 200 mg. and 300 mg., in bottles of 50; in Single Unit Packages of 100 (intended for institutional use only). Injection, 25 mg./ml.; Syrup, 10 mg./5 ml.; Suppositories, 25 mg. and 100 mg.; Concentrate (intended for institutional use only), 30 mg./ml. and 100 mg./ml.

Information for Contributors

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in duplicate to Francis J. Braceland, M.D., Editor, *The American Journal of Psychiatry*, 1700 Eighteenth Street, N.W., Washington, D.C. 20009. Authors of numbered papers presented at the Association's annual meeting should submit two copies of the manuscript to the secretary of the session or notify the secretary that the manuscript will be sent to the *Journal* office later.

All numbered annual meeting papers become the property of the *Journal* although, due to space limitations, fewer than half can be published in the *Journal*. Release of a manuscript for publication elsewhere must be secured from the Editor.

Communications about a manuscript, by letter or telephone, should include reference to the manuscript number. In the case of annual meeting papers, this is the number carried in the program booklet; with other manuscripts, it is the number noted in the letter acknowledging receipt of the manuscript.

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material and that they are not being considered for publication elsewhere. Once a paper has been published in the *Journal*, which is a copyrighted publication, the legal ownership of all parts of the paper, including any illustrations, passes from the author to the *Journal*. If an individual or organization wishes to reprint material published in the *Journal*, written permission must first be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Washington, D.C. 20009; there will usually be a charge for granting this permission.

Informed consent. Manuscripts that report the results of experimental investigation on human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure had been fully explained.

Manuscripts are accepted on condition that the Editor be given the right to make revisions aimed at greater conciseness and clarity and to bring the manuscript into conformity with *Journal* style regarding capitalization, punctuation, etc.

All measurements must be in metric units.

The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not reflect the official attitude or position of the American Psychiatric Association or of the *Journal's* Editorial Board.

SPECIFICATIONS FOR MANUSCRIPTS

Manuscripts should be typed in upper and lower case on one side only of letter-size bond (or other opaque) paper. All parts of the manuscript (including case reports, footnotes, references, etc.) should be double-spaced, with generous margins. Subheads should be inserted at reasonable intervals. Abbreviations not easily recognized by the average reader should be explained.

Length. As a general rule the manuscript of a regular article should not exceed 10–12 typed pages, unless a special arrangement has been made with the Editor; Brief Communications should not exceed 8 typed pages. Letters to the Editor should not exceed 500 words unless a special arrangement has been made with the Editor.

Author identification. The authors' affiliations and position titles should be provided and an address and telephone number given for the first-named author or the coauthor who has print requests. The number of authors should be limited to principal researchers and writers, with other collaborators being acknowledged in a footnote.

Precis. A brief precis is included at the beginning of each article: 60–100 words for regular articles, 40–60 words for Brief Communications. The author may prepare the precis himself or ask that the *Journal* staff prepare it.

References. References should be typed double-spaced on a separate sheet of paper, to be attached at the end of the manuscript. They should be arranged according to their order of appearance in the text, where they should be indicated by numbers in parentheses. Reference citations should be restricted to closely pertinent papers; a complete review of the literature is rarely desirable, except in the case of review articles for which a special arrangement has been made with the Editor.

References should be typed in accordance with the style shown below for books and journal articles; chapters in books will be treated as journal articles with regard to capitalization. Up to three authors should be listed; one or more authors past the third will be designated "et al." Abbreviations of journal names should conform to the syle used in *Index Medicus*.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Schildkraut JJ: Tranylcypromine: effects on norepinephrine metabolism in rat brain. Am J Psychiatry 126:925–931, 1970
3. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349–365, 1967
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968, pp 1–12

Tables and figures. Tables and figures should be self-explanatory and should supplement, not duplicate, the text. See recent issues of the *Journal* for the general requirements of style.

Each table should be typed on a separate sheet, attached at the end of the manuscript. The data should be arranged so that columns of like material read down, not across.

A complete set of figures, preferably in the form of glossy prints, should accompany each of the two copies of the paper. Most figures will be reduced to about 3¼ inches in width; all elements of a figure should be prepared to withstand this reduction. Graphs should be finished drawings not requiring further artwork. Authors are urged to engage the services of a professional in the preparation of figures. Authors may be required to meet the costs of any further artwork that must be done in the editorial office.

AUTHORS' CORRECTIONS

After the paper has been scheduled for publication, the edited manuscript will be sent to the first-named author for corrections and answers to queries. Prompt return is necessary to ensure publication in the assigned month. If an author expects to be away from his office for a long period of time after being notified of the acceptance of his paper, he should inform the *Journal* office or arrange with a coauthor to assume responsibility for the paper. Galley proofs will not be sent to authors.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to authors prior to publication of their papers. Reprints are usually mailed to authors about a month after publication of the article. Requests from others to order reprints should be directed to the Editor; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such

One for the road.

Drunken driving is the cause of an estimated 28,000 auto accident deaths each year—approximately half of these fatal accidents involve an alcoholic. This is only one aspect of the staggering problem represented by alcoholism—perhaps this country's most neglected disease.

Yet, it needn't be, for alcoholism is treatable. Through early detection and treatment of the alcoholic, as well as the use of community resources, physicians can exert a major force in the control and reduction of alcoholism.

ANTABUSE (disulfiram) can help. It offers strong deterrent action...helping alcoholic patients maintain a state of sobriety, while they participate in a total treatment program. Your patient should know the consequences of even a single drink while taking this medication. ANTABUSE works by blocking the normal degradation of alcohol, sharply increasing the concentration of acetaldehyde in the blood by 5 to 10 times, and setting off a most unpleasant, though temporary reaction.

ANTABUSE helps strengthen your patient's resolve...while you help with his underlying problem. On ANTABUSE therapy, the alcoholic patient functions more effectively—not only behind the wheel, but also at work and at home.

BRIEF SUMMARY
(For full prescribing information, see package circular.)
ANTABUSE® (disulfiram) In Alcoholism
INDICATION: ANTABUSE is an aid in the management of selected chronic alcoholic patients who want to remain in a state of enforced sobriety so that supportive and psychotherapeutic treatment may be applied to best advantage. (Used alone, without proper motivation and without supportive therapy, ANTABUSE is not a cure for alcoholism, and it is unlikely that it will have more than a brief effect on the drinking pattern of the chronic alcoholic.)
CONTRAINDICATIONS: Patients who are receiving or have recently received metronidazole, paraldehyde, alcohol, or alcohol-containing preparations, *e.g.* cough syrups, tonics, and the like, should not be given ANTABUSE.
ANTABUSE is contraindicated in the presence of severe myocardial disease or coronary occlusion, psychoses, or hypersensitivity.

WARNINGS: ANTABUSE should never be administered to a patient when he is in a state of alcohol intoxication or without his full knowledge.
The physician should instruct relatives accordingly.

The patient must be fully informed of the ANTABUSE-alcohol reaction. He must be strongly cautioned against surreptitious drinking while taking the drug, and he must be fully aware of possible consequences. He should be warned to avoid alcohol in disguised form, *i.e.* in sauces, vinegars, cough mixtures, and even aftershave lotions and back rubs. He should also be warned that reactions may occur with alcohol up to 14 days after ingesting ANTABUSE.
THE ANTABUSE-ALCOHOL REACTION:
ANTABUSE plus alcohol, even small amounts, produces flushing, throbbing in head and neck, throbbing headache, respiratory difficulty, nausea, copious vomiting, sweating, thirst, chest pain, palpitation, dyspnea, hyperventilation, tachycardia, hypotension, syncope, marked uneasiness, weakness, vertigo, blurred vision, and confusion. In severe reactions there may be respiratory depression, cardiovascular collapse, arrhythmias, myocardial infarction, acute congestive heart failure, unconsciousness, convulsions, and death.
The intensity of the reaction varies with each individual, but is generally proportional to the amounts of ANTABUSE (disulfiram) and alcohol ingested. Mild reactions may occur in the sensitive individual when the blood alcohol concentration is increased to as little as 5 to 10 mg. per 100 cc. Symptoms are fully developed at 50 mg. per 100 cc., and unconsciousness usually results when the blood alcohol level reaches 125 to 150 mg.
The duration of the reaction varies from 30 to 60 minutes to several hours in the more severe cases, or as long as there is alcohol in the blood.
DRUG INTERACTIONS: Disulfiram appears to decrease the rate at which certain drugs are metabolized and so may increase the blood levels and the possibility of clinical toxicity of drugs given concomitantly.
Disulfiram should be used with caution in those patients receiving diphenylhydantoin and its congeners, since toxic levels of these antiepileptic agents have been reported during concomitant disulfiram therapy.
It may be necessary to adjust the dosage of oral anticoagulants upon beginning or stopping disulfiram, since disulfiram may prolong prothrombin time.
Patients taking isoniazid when disulfiram is given should be observed for the appearance of unsteady gait or marked changes in mental status and the disulfiram discontinued if such signs appear.
CONCOMITANT CONDITIONS: Because of the possibility of an accidental ANTABUSE-alcohol reaction, ANTABUSE (disulfiram) should be used with extreme caution in patients with any of the following conditions: diabetes mellitus, hypothyroidism, epilepsy, cerebral damage, chronic and acute nephritis, hepatic cirrhosis or insufficiency.
USAGE IN PREGNANCY: The safe use of this drug in pregnancy has not been established. Therefore, ANTABUSE should be used during pregnancy only when, in the judgment of the physician, the probable benefits outweigh the possible risks.
PRECAUTIONS: It is suggested that every patient under treatment carry an Identification Card, stating that he is receiving ANTABUSE and describing the symptoms most likely to occur as a result of the ANTABUSE-alcohol reaction. In addition, this card should indicate the physician or institution to be contacted in emergency. (Cards may be obtained from Ayerst Laboratories upon request.)
Alcoholism may accompany or be followed by dependence on narcotics or sedatives. Barbiturates have been administered concurrently with ANTABUSE (disulfiram) without untoward effects, but the possibility of initiating a new abuse should be considered.
Base line and follow-up transaminase tests (10-14 days) are suggested to detect any hepatic dysfunction that may result with ANTABUSE therapy. In addition, a complete blood count and a sequential multiple analysis-12 (SMA-12) test should be made every six months.
ADVERSE REACTIONS: (See Contraindications, Warnings, and Precautions.)
Optic neuritis, peripheral neuritis, and polyneuritis may occur following administration of ANTABUSE.
Occasional skin eruptions are, as a rule, readily controlled by concomitant administration of an antihistaminic drug.
In a small number of patients, a transient mild drowsiness, fatigability, impotence, headache, acneform eruptions, allergic dermatitis, or a metallic or garlic-like aftertaste may be experienced during the first two weeks of therapy. These complaints usually disappear spontaneously with the continuation of therapy or with reduced dosage.
Psychotic reactions have been noted, attributable in most cases to high dosage, combined toxicity (with metronidazole or isoniazid), or to the unmasking of underlying psychoses in patients stressed by the withdrawal of alcohol.
One case of cholestatic hepatitis has been reported, but its relationship to ANTABUSE has not been unequivocally established.
DOSAGE AND ADMINISTRATION: ANTABUSE (disulfiram) should never be administered until the patient has abstained from alcohol for at least 12 hours.
INITIAL DOSAGE SCHEDULE: In the first phase of treatment, a maximum of 500 mg. daily is given in a single dose for one to two weeks. Although usually taken in the morning, ANTABUSE may be taken on retiring by patients who experience a sedative effect. Alternatively, to minimize, or eliminate, the sedative effect, dosage may be adjusted downward.
MAINTENANCE REGIMEN: The average maintenance dose is 250 mg. daily (range, 125 to 500 mg.); it should not exceed 500 mg. daily.
NOTE: Occasional patients, while seemingly on adequate maintenance doses of ANTABUSE, report that they are able to drink alcoholic beverages with impunity and without any symptomatology. All appearances to the contrary, such patients must be presumed to be disposing of their tablets in some manner without actually taking them. Until such patients have been observed reliably taking their daily ANTABUSE tablets (preferably crushed and well mixed with liquid), it cannot be concluded that ANTABUSE is ineffective.
DURATION OF THERAPY: The daily, uninterrupted administration of ANTABUSE must be continued until the patient is fully recovered socially and a basis for permanent self-control is established. Depending on the individual patient, maintenance therapy may be required for months or even years.
TRIAL WITH ALCOHOL: During early experience with ANTABUSE, it was thought advisable for each patient to have at least one supervised alcohol-drug reaction. More recently, the test reaction has been largely abandoned. Furthermore, such a test reaction should never be administered to a patient over 50 years of age. A clear, detailed, and convincing description of the reaction is felt to be sufficient in most cases.
However, where a test reaction is deemed necessary, the suggested procedure is as follows:
After the first one to two weeks' therapy with 500 mg. daily, a drink of 15 cc. (1/2 oz.) of 100 proof whiskey or equivalent is taken slowly. This test dose of alcoholic beverage may be repeated once only so that the total dose does not exceed 30 cc. (1 oz.) of whiskey. Once a reaction develops, no more alcohol should be consumed. Such tests should be carried out only when the patient is hospitalized, or comparable supervision and facilities, including oxygen, are available.
MANAGEMENT OF ANTABUSE (DISULFIRAM)-ALCOHOL REACTION: In severe reactions, whether caused by an excessive test dose or by the patient's unsupervised ingestion of alcohol, supportive measures to restore blood pressure and treat shock should be instituted. Other recommendations include: oxygen, carbogen (95 per cent oxygen and 5 per cent carbon dioxide), vitamin C intravenously in massive doses (1 Gm.), and ephedrine sulfate. Antihistamines have also been used intravenously. Potassium levels should be monitored particularly in patients on digitalis since hypokalemia has been reported.
HOW SUPPLIED: No. 809—Each tablet (scored) contains 250 mg. disulfiram, in bottles of 100.
No. 810—Each tablet (scored) contains 500 mg. disulfiram, in bottles of 50 and 1,000. **7626**

A first step in rehabilitation of the alcoholic

Ayerst®
AYERST LABORATORIES
New York, N.Y. 10017

in clinically significant depression...

penetrating the symptom barrier to productive psychotherapy

symptoms often interfere with therapy

In clinically significant depression, the patient often becomes barricaded behind his own symptoms during psychotherapy. Because these symptoms can be so sharply defined and somatic in expression, he may reject the fact that they are psychic in origin. Sleep disturbance, gastrointestinal complaints, anorexia, chronic fatigue, and other psychosomatic symptoms may so preoccupy—or overwhelm—the depressed patient that truly productive therapeutic sessions are difficult to achieve. Instead of being able to concentrate on the core emotional problems of the depression itself, he may for example go on at length about how broken his sleep is or keep reiterating (while the therapeutic hour slips by) how physically miserable he feels.

ELAVIL®
(AMITRIPTYLINE HCl, MSD)
to help penetrate the symptom barrier in depression requiring medication

ELAVIL, a highly effective tricyclic antidepressant, will often alleviate these symptoms. With the help of ELAVIL, sleep disturbance—so common in clinically depressed patients and often the symptom that distresses them most—as

well as other "barrier symptoms" may be lessened to the point where they no longer come between you and the patient.

psychotherapy takes direction

As these preoccupying complaints are lifted, psychotherapy sessions can become more productive. Patients are enabled to respond more fruitfully during therapeutic hours and to resume or pursue more efficiently the necessary activities in their personal lives.

meeting therapeutic goals

And as the antidepressant activity of ELAVIL (Amitriptyline HCl, MSD) takes hold, it helps relieve the depressive condition itself. Sometimes only a minimum of actual psychotherapy is required. The patient may experience a more rapid recovery—while you conserve valuable time.

Prescribe ELAVIL then, to help lighten the patient's burden in depression—and yours in its management.

ELAVIL should not be used during the acute recovery phase following myocardial infarction; in patients hypersensitive to it; in those who have received an MAOI within two weeks; or in children under 12. Patients with cardiovascular disorders should be watched closely. Its safe use during pregnancy and lactation has not been established. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol. Since suicide is a possibility in any depressive illness, patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

TABLETS: 10 mg, 25 mg, 50 mg, 75 mg, and 100 mg
INJECTION: 10 mg per ml

ELAVIL®
(AMITRIPTYLINE HCl | MSD)

an antidepressant with an anxiety-reducing sedative component to its action

MSD
MERCK SHARP & DOHME

For a brief summary of prescribing information, please see following page.

MSD
MERCK SHARP & DOHME

addendum

ELAVIL®

(AMITRIPTYLINE HCl | MSD)

Five tablet strengths for differing patient needs. The variety of dosage strengths available with ELAVIL makes possible great prescribing flexibility.

Once-a-day dosage at bedtime is an appropriate way to start—and maintain—many patients on therapy. The simplicity of this regimen helps improve patient compliance. ELAVIL may also be prescribed in divided daily doses.

A sedative effect may be apparent before the antidepressant effect of ELAVIL is noted. An adequate therapeutic effect may take as long as 30 days to develop.

100 mg
75 mg
50 mg

These tablets may be advantageous when initiating therapy with once-daily bedtime dosage in adult outpatients. The usual starting dosage is 75 mg daily. Therapy may be initiated with 50 to 100 mg daily. This may be increased by 25 or 50 mg as necessary in the bedtime dose to a total of 150 mg per day.

These tablets may also be convenient for many hospitalized patients. These patients may need 100 mg a day initially which can be increased gradually to 200 mg a day if necessary. A small number of such patients may need as much as 300 mg a day.

25 mg 

This tablet may prove useful when initiating therapy with divided daily doses in adult outpatients. Starting dosage is usually 75 mg daily. If necessary, this dosage may be increased gradually to a total of 150 mg a day. Increases are made preferably in the late afternoon or bedtime doses.

10 mg 

Because lower doses are generally recommended for adolescents and elderly patients, the 10-mg tablets may be most serviceable. Ten mg three times a day with 20 mg at bedtime may be satisfactory in adolescent and elderly patients who do not tolerate higher doses.

NOTE: The usual maintenance dosage of ELAVIL is 50 to 100 mg per day which may be given in a single dose preferably at bedtime. In some patients 40 mg per day is sufficient. This drug is not recommended for patients under 12 years of age.

Contraindications: Known hypersensitivity. Should not be given concomitantly with a monoamine oxidase inhibitor or within at least 14 days following the discontinuance of a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred. When used to replace a monoamine oxidase inhibitor, initiate dosage of amitriptyline HCl cautiously with gradual increase in dosage until optimum response is achieved. Not recommended during the acute recovery phase following myocardial infarction.

Warnings: May block the antihypertensive action of guanethidine or similarly acting compounds. Should be used with caution in patients with a history of seizures or urinary retention, or with angle-closure glaucoma or increased intraocular pressure; in patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely; arrhythmias, sinus tachycardia and prolongation of the conduction time have been reported, particularly with high doses; myocardial infarction and stroke have been reported with drugs of this class. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. Safe use during pregnancy and lactation has not been established; in pregnant patients, nursing mothers, or women who may become pregnant, weigh possible benefits against possible hazards to mother and child. Not recommended for patients under 12 years of age.

Precautions: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances, the dose of amitriptyline HCl may be reduced or a major tranquilizer, such as perphenazine, may be administered concurrently.
When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required; paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs. Use cautiously in patients receiving large doses of ethchlorvynol, since transient delirium has been reported on concurrent administration. May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains during treatment and until significant remission occurs; this type of patient should not have access to large quantities of the drug. Concurrent electroshock therapy may increase the hazards associated with such therapy; such treatment should be limited to patients for whom it is essential. When possible, discontinue the drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use with caution in patients with impaired liver function.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions not reported with this specific drug. However, pharmacological similarities among the tricyclic antidepressant drugs require that each reaction be considered when amitriptyline is administered. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue, rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise; these are not indicative of addiction.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.

How Supplied: Tablets containing 10 mg and 25 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100, 1000, and 5000; tablets containing 50 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100 and 1000; tablets containing 75 mg and 100 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100; for intramuscular use, in 10-ml vials containing per ml: 10 mg amitriptyline HCl, 44 mg dextrose, 1.5 mg methylparaben and 0.2 mg propylparaben as preservatives, and water for injection q.s. 1 ml.

MSD
MERCK SHARP & DOHME

When a period of intensive residential treatment is indicated: THE BROWN SCHOOLS

A community within a community to provide individualized treatment within a residential milieu.

A program designed for: psychiatric illness, behavior problems in neurological patients, and rehabilitation of the mentally retarded.

Three separate treatment centers plus a transitional treatment center provide individually prescribed programs of care, education, treatment and training for children, adolescents and adults. The centers are geographically separated to provide the proper residential group, yet near enough to benefit from the combined training and experience of a wide range of staff members.

For information, write: The Director of Admissions, Department C-0, THE BROWN SCHOOLS, P.O. Box 4008, Austin, Texas 78765

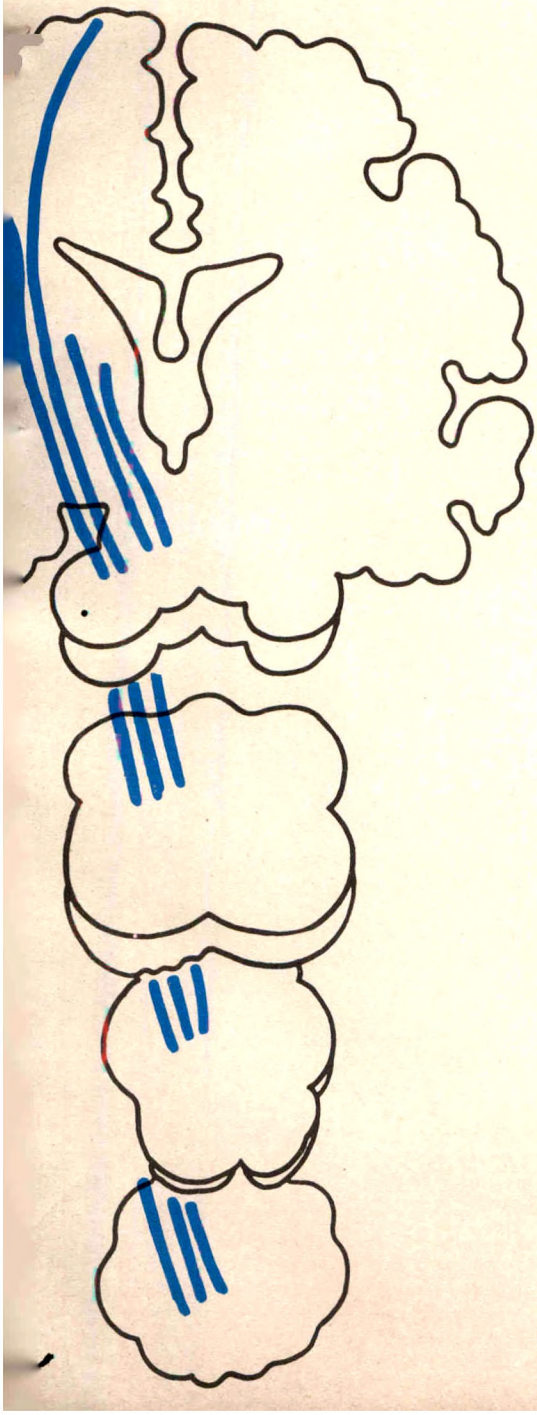
Norepinephrine deficiency



Rendition of the aminergic pathways thought to be involved in affective disorders—norepinephrine (blue), dopamine (magenta), and serotonin (orange). Norepinephrine (blue) is most closely allied to depressive states.

...in depression*

Pertofrane®

☐ raises norepinephrine levels

☐ effectively relieves symptoms

Theory

☐ Recent research has shown that depression may be associated with a deficiency of brain norepinephrine.[1] This thesis is supported by findings that certain depressive disorders respond when norepinephrine levels are increased.

Fact

☐ Pertofrane is a monomethylated tricyclic and possesses greater ability to raise brain norepinephrine levels at the synapse than dimethylated forms such as imipramine and amitriptyline.[2,3]

☐ Clinical experience with Pertofrane has shown rapid onset of action...relief of associated mild anxiety/agitation...mid-range sedation...and compatibility with tranquilizers and sedatives. Pertofrane is available in 25 and 50 mg. capsules. Usual dosage: one capsule t.i.d.

Pertofrane®
(desipramine hydrochloride NF)

When activity is important

USV PHARMACEUTICALS

USV Pharmaceutical Mfg. Corp.
Manati, P.R. 00701

*Not all depressions are associated with deficiencies of norepinephrine as measured by MHPG.

Please see next page for brief summary of prescribing information and references.

Pertofrane®
(desipramine HCl)
When activity is important

Indication: For relief of mental depression. **Contraindications:** Do not use MAO inhibitors concomitantly or within 2 weeks of the use of this drug. Hyperpyretic crises or severe convulsive seizures may occur with such combinations; potentiation of adverse reactions can be serious or even fatal. When substituting Pertofrane (desipramine HCl) in patients receiving an MAO inhibitor, allow an interval of at least 14 days. Initial dosage in such patients should be low and increases should be gradual and cautiously prescribed. The drug is contraindicated following recent myocardial infarction and in patients with a known hypersensitivity to tricyclic antidepressants. **Warnings:** Activation of psychosis may occasionally be observed in schizophrenic patients. Due to atropine-like effects and sympathomimetic potentiation, use only with the greatest care in patients with narrow-angle glaucoma or urethral or ureteral spasm. Do not use in patients with the following conditions unless the need outweighs the risk: severe coronary heart disease with EKG abnormalities, progressive heart failure, angina pectoris, paroxysmal tachycardia and active seizure disorder (may lower seizure threshold). This drug may block the action of the antihypertensive, guanethidine, and related adrenergic neuron-blocking agents. Hypertensive episodes have been observed during surgery. The concurrent use of other central nervous system drugs or alcohol may potentiate adverse effects. Since many such drugs may be used during surgery, desipramine should be discontinued prior to elective procedures. Caution patients on the possibility of impaired ability to operate a motor vehicle or dangerous machinery. Do not use in women who are or may become pregnant, or in children under 12 years of age, unless the clinical situation warrants the potential risk. Because of increased sensitivity to the drug, use lower than normal dosage in adolescent and geriatric patients. **Precautions:** Potentially suicidal patients require careful supervision and protective measures during therapy. Prescriptions should be limited to small quantities. Discontinuation of the drug may be necessary in the presence of increased agitation and anxiety shifting to hypomanic or manic excitement. Atropine-like effects may be more pronounced (e.g. paralytic ileus) in susceptible patients and in those receiving anticholinergic drugs (including antiparkinsonism agents). Prescribe cautiously in hyperthyroid patients and in those receiving thyroid medications; transient cardiac arrhythmias have occurred in rare instances. Periodic blood and liver studies should supplement careful clinical observations in all patients undergoing extended courses of therapy. **Adverse Reactions:** The following have been reported: *Nervous System:* dizziness, drowsiness, insomnia, headache, disturbed visual accommodation, tremor, unsteadiness, tinnitus, paresthesias, changes in EEG patterns, epileptiform seizures, mild extrapyramidal activity, falling and neuromuscular incoordination. A confusional state (with such symptoms as hallucinations and disorientation), particularly in older patients and at higher dosage, may require discontinuation of the drug. *Gastrointestinal Tract:* anorexia, dryness of the mouth, nausea, epigastric distress, constipation and diarrhea. *Skin:* skin rashes (including photosensitization), perspiration and flushing sensations. *Liver:* rare cases of transient jaundice(apparently of an obstructive nature) and liver damage. If jaundice or abnormalities in liver function tests occur, discontinue the drug and investigate. *Blood Elements:* bone-marrow depression, agranulocytosis, thrombocytopenia and purpura. If these occur, discontinue the drug. Transient eosinophilia has been observed. *Cardiovascular System:* orthostatic hypotension and tachycardia. Carefully supervise patients requiring concomitant vasodilating therapy, particularly during initial phases. *Genitourinary System:* urinary frequency or retention and impotence. *Endocrine System:* occasional hormonal effects, including gynecomastia, galactorrhea and breast enlargement, and decreased libido and estrogenic effect. *Sensitivity:* urticaria and rare instances of drug fever and cross-sensitivity with imipramine. **Dosage:** All patients except geriatric and adolescent: 50 mg. t.i.d. (150 mg. daily). Dosage may be increased up to 200 mg. daily. Geriatric and adolescent patients should usually be started with lower dosage (25 to 50 mg. daily) and may not tolerate higher doses. Dosage may be increased up to 100 mg. daily. Lower maintenance dosages should be continued for at least 2 months after obtaining a satisfactory response. Mild anxiety and agitation which may accompany depression usually remit as the depression responds. Occasionally, however, a sedative or tranquilizer may be indicated. **How Supplied:** 25 mg. capsules (pink), bottles of 100 and 1000. Also, 50 mg. capsules (maroon and pink), bottles of 100 and 1000.

Now... once-a-day antidepressant dosage with an a.m. or h.s. option

Norpramin®
(desipramine hydrochloride tablets NF) 25 mg., 50 mg. tablets

(See following pages for prescribing information

New flexible administration to help the depressed patient

Clinical studies show that a single daily administration of Norpramin is as effective and well tolerated as the same quantity given as a divided dosage. This means that Norpramin may be given once daily—morning or bedtime—at a time most appropriate to the patient's therapeutic need, drug response and activity patterns.

a.m. dosage may be preferred

For patients who feel more depressed in the morning and want to take their medication at that time, Norpramin can help patients get started with their daily responsibilities and encourage participation in various forms of psychotherapy.

To reduce the potential for confusion in medication schedules when other agents are prescribed concomitantly at bedtime.

For patients in hospitals and nursing homes where there may be greater availability of staff qualified to administer medication during morning hours.

h.s. dosage may be preferred

Bedtime dosage may be particularly appropriate for patients who experience significant sedation, or when bedtime dosage best suits individual activity patterns. Administration of Norpramin at night rarely produces morning hangover.

Norpramin®
(desipramine hydrochloride tablets NF)

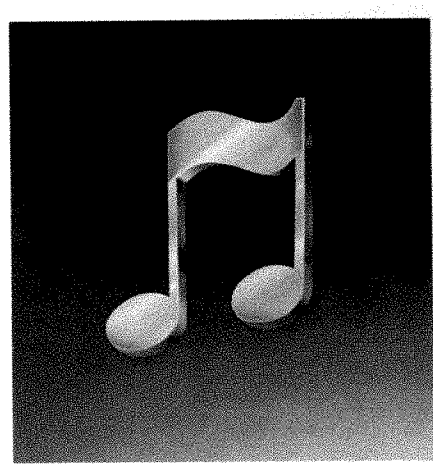
Brief Summary
Indications: Norpramin (desipramine hydrochloride tablets NF) is indicated for the relief of depressive symptoms. Endogenous depressions are more likely to be alleviated than others.
Contraindications: Desipramine hydrochloride should not be given within two weeks of treatment with a monoamine oxidase inhibitor. Contraindications include the acute recovery period following myocardial infarction and hypersensitivity to the drug. Cross sensitivity with other dibenzazepines is a possibility.
Warnings: 1. Extreme caution should be used in patients: (a) with cardiovascular disease, (b) with a history of urinary retention or glaucoma, (c) with thyroid disease or those on thyroid medication, (d) with a history of seizure disorder. 2. This drug is capable of blocking the antihypertensive effect of guanethidine and similarly acting compounds. 3. *Use in Pregnancy:* Safe use during pregnancy and lactation has not been established. 4. *Use in Children:* Norpramin is not recommended for use in children. 5. This drug may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. Therefore, the patient should be cautioned accordingly.
Precautions: This drug should be dispensed in the least possible quantities to depressed outpatients, since suicide has been accomplished with drugs of this class. If possible, dispense in child-resistant containers. It should be kept out of reach of children. Reduce dosage, or alter treatment, if serious adverse effects occur. Norpramin therapy in patients with manic-depressive illness may induce a hypomanic state after the depressive phase terminates and may cause exacerbation of psychosis in schizophrenic patients. Use cautiously with anticholinergic or sympathomimetic drugs. Response to alcoholic beverages may be exaggerated. In the concurrent administration of ECT and antidepressant drugs one should consider the possibility of increased risk relative to benefits. Discontinue as soon as possible prior to elective surgery because of possible cardiovascular effects. Hypertensive episodes have been observed during surgery in patients on desipramine hydrochloride. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is neutropenia.

function actively

Early therapeutic response— builds hope and provides encouragement

While full therapeutic effect may require two to three weeks, onset of action has often been observed in two to five days. Although results have been variable, the weight of scientific reports suggests a faster onset of action with desipramine than with either imipramine or amitriptyline.

Divided or once-a-day dosage with an a.m. or h.s. option



Usual Adult Dose:

The usual adult dosage is 100 to 200 mg. per day. Dosage should be initiated at a lower level and increased according to tolerance and clinical response to a maximum of 200 mg. daily.

Dosages above 200 mg. per day are not recommended. Initial therapy may be administered in divided doses or a single daily dose.

Maintenance therapy may also be given on a once daily schedule for patient convenience and better compliance.

See prescribing information for geriatric and adolescent dosage.

Norpramin®

(desipramine hydrochloride tablets NF) 25 mg., 50 mg. tablets

lightens and brightens the days of your depressed patients— more conveniently

Adverse Reactions: *Cardiovascular:* hypotension, ypertension, tachycardia, palpitation, arrhythmias, eart block, myocardial infarction, stroke. *Psychiatric:* onfusional states (especially in the elderly), hallu- inations, disorientation, delusions; anxiety, restless- ess, agitation; insomnia and nightmares; hypomania; xacerbation of psychosis. *Neurological:* numbness, ngling, paresthesias of extremities; incoordination, taxia, tremors; peripheral neuropathy; extrapyramidal ymptoms; seizures; alteration in EEG patterns; tinni- us. *Anticholinergic:* dry mouth, and rarely associated ublingual adenitis; blurred vision, disturbance of ccommodation, mydriasis; constipation, paralytic eus; urinary retention, delayed micturition, hypotonic ladder. *Allergic:* skin rash, petechiae, urticaria, itch- photosensitization, edema (of face and tongue general), drug fever, cross sensitivity with other tricyclic drugs. *Hematologic:* bone marrow depressions including agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* anorexia, nausea and vomiting, epigastric distress, peculiar taste, abdominal cramps, diarrhea, stomatitis, black tongue. *Endocrine:* gynecomastia, breast enlargement and galactorrhea in the female; increased or decreased libido, impotence, testicular swelling; elevation or depression of blood sugar levels. *Other:* jaundice (simulating obstructive), altered liver function; weight gain or loss, perspiration, flushing; urinary frequency, nocturia; parotid swelling; drowsiness, dizziness, weakness and fatigue, headache; alopecia. *Withdrawal Symptoms:* Though not indicative of addiction, abrupt cessation after prolonged therapy may produce nausea, headache and malaise.

Dosage and Administration: *Usual adult dose:* 100 mg. to 200 mg. per day. Dosages above 200 mg. per day are not recommended. *Initial therapy:* Should be administered at a low level and increased according to tolerance and response. It may be administered in divided doses or a single daily dose. *Maintenance:* Lower adequate dose once daily to maintain remission. *Adolescent and geriatric patient dose:* 25 mg. to 100 mg. per day, in single or divided doses. Dosages above 100 mg. are not recommended.

A Psychiatric Glossary

Edited by a subcommittee of the AMERICAN PSYCHIATRIC ASSOCIATION Committee on Public Information.

The new Fourth Edition marks a striking expansion of definitions: 400 terms have been added and many of the terms appearing in earlier editions have received revised explanations. In addition to the GLOSSARY's continuing value to lawyers, teachers, journalists, social workers, and others, the new edition will be useful to medical students and first year residents in psychiatry.

Some major changes in the Fourth Edition:

- Expansion from 102 to 156 pages to accommodate 400 new terms
- New tables of terms in seven areas of contemporary concern
  - Drugs Used in Psychiatry
  - Legal Terms
  - Neurologic Deficits
  - Psychological Tests
  - Research Terms
  - Schools of Psychiatry
  - Sleep Disorders
- A comprehensive set of terms used in behavior therapy is included for the first time.

Paperback edition—$3.00 each, (See coupon for bulk discounts), may be ordered from the AMERICAN PSYCHIATRIC ASSOCIATION, Publications Sales, 1700 18th St. N.W., Washington, D.C. 20009.

Hardback edition—$7.95 may be ordered from Basic Books, Inc., 10 East 53rd Street, New York, New York 10022.

LIBRIUM®
(chlordiazepoxide HCl)
5 mg, 10 mg, 25 mg capsules

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Supplied: Librium® Capsules containing 5 mg, 10 mg or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.

ROCHE

Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, New Jersey 07110

EXPERIENCE. STILL YOUR HIGHEST AUTHORITY.

The discovery of Librium at Hoffmann-La Roche represented a landmark in psychotherapeutics. And, more specifically, a landmark in the treatment of anxiety and anxiety-related conditions.

Today, the acceptance of Librium by the medical community is based firmly on experience. And on a well-documented clinical record.

A record so voluminous it had to be put into a computerized storage and retrieval system.

Take the matter of safety, for example.

Experience with millions of patients indicates that the most common side effects of Librium are dose-related and, therefore, largely avoidable. There appears to be a low potential for dependence. Tolerance rarely develops. Few cases of known toxicity have been reported. However, patients should be cautioned about possible combined effects with alcohol and other CNS depressants.

Librium seldom produces adverse effects on the cardiovascular or respiratory

system. It is used concomitantly with many primary medications, such as cardiac glycosides, antihypertensive agents, anticholinergics, diuretics, antacids and anticoagulants. It should be noted that variable effects on blood coagulation have been reported very rarely in patients receiving Librium and oral anticoagulants; however, a causal relationship has not been established clinically.

Experience. Yours and ours. Together they make the task of choosing an antianxiety agent much simpler.

THE ANXIETY-SPECIFIC

Please see summary of product information on opposite page.

Schizophrenia

by Royal Doulton

There is a brooding quality to the figure. She seems lost in her world, cut off from reality, perhaps suspicious, withdrawn and anxious...suggestively schizophrenic in demeanor.

Actual title: 'Romance'. From the Royal Doulton Figurine Collection...one of the many exquisite figures from the master craftsmen of ceramic sculpture, destined to become a collector's item.

Serentil® (mesoridazine)

by Aguilar, *et al.*

"...'hard-core' chronic schizophrenics who have either regressed to a lower level of functioning after initial improvement, or have failed to respond to previous psychotropic medication...can improve significantly [with] Serentil."
Aguilar SJ: Dis Nerv Syst, 36:484, 1975.

"...the onset of mesoridazine's activity can be observed even on the first day of treatment. This rapid onset of action [with the I.M. dosage form] makes mesoridazine valuable in the treatment of psychiatric emergencies."*
Hamid TA and Wertz WJ: Am J Psych 130:689, 1973.

*Because of possible hypotensive effects, parenteral administration should be reserved for bedfast patients or for acute ambulatory cases. Patients should be kept lying down for at least one-half hour after injection.

"...remarkably low incidence of adverse reactions when compared with other phenothiazine compounds."
Serentil Prescribing Information, PDR, 1976.

In prescribing Serentil, observe the same precautions as with other phenothiazines, including awareness of all adverse reactions observed with them. (As with other phenothiazines, patients refractory to previous medications may respond to Serentil.)
Please see next page for a brief summary of the prescribing information, including contraindications and adverse reactions.

Serentil® (mesoridazine) as the besylate

Available in 3 dosage forms: Tablets: 10, 25, 50 and 100 mg. Concentrate: 25 mg/cc. Injectable: 1 cc (25 mg).

—Side effects are usually mild or moderate.

—Except for tremor and rigidity, adverse reactions are usually found in patients receiving high doses early in treatment.

—Low incidence of Parkinson's syndrome.

—Drowsiness and hypotension are the most prevalent side effects encountered.

Indication: Schizophrenia.

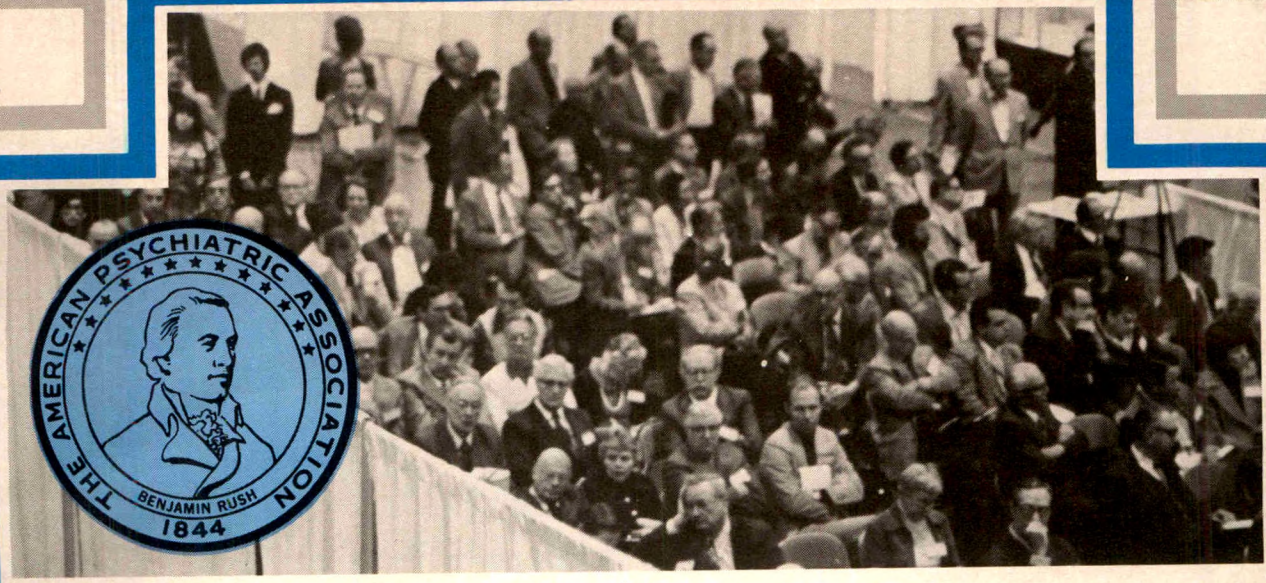
Contraindications: Severe central nervous system depression, comatose states and hypersensitivity to the drug.

Warnings: Administer cautiously and increase dosage gradually to patients participating in activities requiring complete mental alertness (e.g., driving). The safety of this drug in pregnancy has not been established; hence it should be given only when the anticipated benefits exceed the possible risk to mother and fetus. Not recommended for use in children under 12 years of age since safe conditions for this use have not been established. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides.

Precautions: Ocular changes have been seen with other phenothiazines but, to date, have not been related to mesoridazine. Because of possible hypotensive effects, reserve parenteral administration for bedfast patients or acute ambulatory cases, and keep patient lying down for at least one-half hour after injection. Leukopenia and/or agranulocytosis have been attributed to phenothiazine therapy. A single case of transient granulocytopenia has been associated with mesoridazine. Patients receiving anticonvulsant medication should be continued on that regimen while receiving mesoridazine to prevent possible convulsive seizures. As with most medications, the dosage of mesoridazine should be adjusted to the needs of the individual and the lowest effective dosage should always be used.

Adverse Reactions: Mesoridazine has demonstrated a remarkably low incidence of adverse reactions compared with other phenothiazine compounds. Drowsiness, Parkinson's syndrome, dizziness, weakness, tremor, restlessness, ataxia, dystonia, rigidity, slurring, akathisia, motoric reactions (opisthotonos). Dry mouth, nausea and vomiting, fainting, stuffy nose, photophobia, constipation and blurred vision have occurred. Inhibition of ejaculation, impotence, enuresis, incontinence. Itching, rash, hypertrophic papillae of the tongue and angioneurotic edema. Hypotension, tachycardia, EKG changes. The following reactions have occurred with

phenothiazines and should be considered: miosis, obstipation, anorexia, paralytic ileus. Erythema, exfoliative dermatitis, contact dermatitis. Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. Fever, laryngeal edema, angioneurotic edema, asthma. Jaundice, biliary stasis. Changes in terminal portion of the EKG, including prolongation of the Q-T interval, lowering and inversion of the T wave and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including mesoridazine. These appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence that these changes are in any way precursors of any significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms would appear to be of questionable value as a predictive device. Hypotension, rarely resulting in cardiac arrest has also been noted. Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonos, oculogyric crises, tremor, muscular rigidity, akinesia. As with all antipsychotics, tardive dyskinesia may appear on long-term therapy or after long-term therapy is discontinued. Risks seem to be greater in elderly patients on high dose therapy, especially females. Discontinue all antipsychotic agents if the symptoms of tardive dyskinesia syndrome appear. (See full prescribing information for description of the symptoms of the tardive dyskinesia syndrome). Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. Retention, incontinence. Hyperpyrexia, behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses and toxic confusional states. Following long-term therapy, a peculiar skin-eye syndrome marked by progressive pigmentation of areas of the skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea. Systemic lupus erythematosus-like syndrome.



How Supplied: *Tablets:* 10 mg., 25 mg., 50 mg. and 100 mg. mesoridazine (as the besylate); packages of 100 and 5000.

Ampuls: 1 cc. [25 mg. mesoridazine (as the besylate).] Inactive ingredients: disodium edetate, U.S.P., 0.5 mg.; sodium chloride, U.S.P., 7.2 mg.; carbon dioxide gas (bone dry) q.s.; water for injection, U.S.P., q.s. to 1 cc.; boxes of 20 and 100. *Concentrate:* 25 mg. mesoridazine (as the besylate) per cc., alcohol, U.S.P., 0.61% by volume. Immediate containers. Amber glass bottles of 4 fl. oz.

For complete details, please see the full prescribing information.

ADAPIN®
(Doxepin HCl)

Capsules, 10 mg., 25 mg., 50 mg.

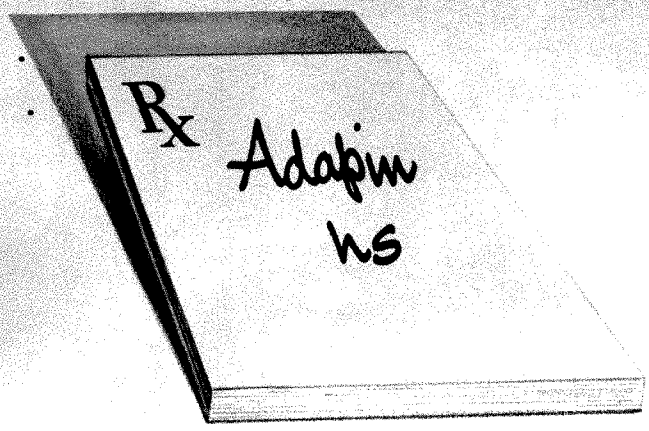
And the Management of Disturbed Sleep Patterns in Anxiety/Depression

Disturbed sleep patterns are a familiar component of the symptom complex seen in patients with anxiety and/or depression.

One study[1] has shown that doxepin [Adapin] is helpful in providing symptomatic relief of sleep disturbances associated with anxiety and depression, "allowing patients to fall asleep more rapidly and feel more rested upon awakening."

Another study[2] points out that doxepin [Adapin] given "at bedtime to outpatients with mixed anxiety and depression will yield as much improvement as can be obtained by giving the drug three times a day."

So, a single dose of Adapin, given at bedtime can often help promote a restful night's sleep for patients with mixed anxiety and depression. Other clinical benefits include:



- rapid antianxiety effect
- distinct clinical brightening of mood—usually within three to four weeks
- low incidence of side effects
- suitability for long-term usage

ADAPIN®

(Doxepin HCl)

Prescribing information:

DESCRIPTION

Adapin (doxepin HCl) is an isomeric mixture of N, N-dimethyl-dibenz(b,e) oxepin- $\Delta^{11(6H)}$, γ propylamine hydrochloride.

ACTIONS

Adapin has a variety of pharmacological actions with its predominant action on the central nervous system. While its mechanism of action is not known, studies have demonstrated that it is neither a monoamine oxidase inhibitor nor a primary stimulant of the central nervous system.

INDICATIONS

In controlled clinical evaluations, **Adapin** has shown marked antianxiety and significant antidepressant effects. **Adapin** has been found to be well tolerated even in elderly patients.

Adapin is indicated for the treatment of patients with:

1. Psychoneurotic anxiety and/or depressive reactions.
2. Mixed symptoms of anxiety and depression.
3. Anxiety and/or depression associated with alcoholism.
4. Anxiety associated with organic disease.
5. Psychotic depressive disorders including involutional depression and manic-depressive reactions.

Target symptoms of psychoneurosis that respond particularly well to **Adapin** include: anxiety, tension, depression, somatic symptoms and concerns, insomnia, guilt, lack of energy, fear, apprehension and worry.

Because **Adapin** provides antidepressant as well as antianxiety effects, it is of particular value in patients in whom anxiety masks depression. Patients who have not responded to other antianxiety or antidepressant drugs may benefit from **Adapin.**

In a large series of patients systematically observed for withdrawal symptoms, none were reported—a finding which is consistent with the virtual absence of euphoria as a side effect and the lack of addictive potential characteristic of this type of chemical compound.

CONTRAINDICATIONS

Because **Adapin** has an anticholinergic effect, it is contraindicated in patients with glaucoma or a tendency toward urinary retention.

Use of **Adapin** is contraindicated in patients who have been found hypersensitive to it.

WARNINGS

Usage in Pregnancy—Adapin has not been evaluated in pregnant patients. Therefore, it should not be used during pregnancy unless, in the judgment of the physician, it is essential to the welfare of the patient.

In animal reproduction studies of **Adapin (doxepin hydrochloride),** gross and microscopic examination of the offspring gave no evidence of drug-related teratogenic effect. Following doses of up to 25 mg./kg./day for 8 to 9 months, no changes were observed in the number of live births, litter size, or lactation. A decreased rate of conception was observed when male rats were given 25 mg./kg./day for prolonged periods—an effect which has occurred with other psychotropic drugs and has been attributed to drug effect on the central and/or autonomic nervous systems.

Usage in Children—The use of **Adapin** in children under 12 years of age is not recommended, because safe conditions for its use have not been established.

MAO Inhibitors—Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with **Adapin.** The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered, and the dosage involved.

PRECAUTIONS

Drowsiness may occur with **Adapin;** therefore, patients should be warned of its possible occurrence and cautioned against driving a motor vehicle or operating hazardous machinery while taking the drug.

Patients should also be cautioned that the effects of alcoholic beverages may be increased.

Since suicide is an inherent risk in depressed patients and remains a risk through the initial phases of improvement, depressed patients should be closely supervised.

Although **Adapin** has shown effective tranquilizing activity, the possibility of activating or unmasking latent psychotic symptoms should be kept in mind.

Compounds structurally related to **Adapin** can block the effects of guanethidine and similarly acting compounds. However, at the usual clinical dosages, 75 mg. to 150 mg. per day, **Adapin** has been given concomitantly with guanethidine without blocking its antihypertensive effect. But at dosages of 300 mg. per day or higher, **Adapin** has exerted a significant blocking effect.

Adapin, like other structurally related psychotropic drugs, potentiates norepinephrine response in animals. But this effect has not been observed with **Adapin** in humans, which is in accord with the low incidence of tachycardia reported clinically.

ADVERSE REACTIONS

Anticholinergic Effects: Dry mouth, blurred vision and constipation have been reported. These are usually mild, and often subside as therapy is continued or dosage reduced.

Central Nervous System Effects: Drowsiness has been observed. It usually occurs early in the course of therapy and tends to subside as therapy continues. (See Dosage and Administration section.)

Cardiovascular Effects: Tachycardia and hypotension have been reported infrequently.

Other infrequently reported adverse effects include extrapyramidal symptoms, gastrointestinal reactions, secretory effects (such as increased sweating), weakness, dizziness, fatigue, weight gain, edema, paresthesias, flushing, chills, tinnitus, photophobia, decreased libido, rash, and pruritus.

DOSAGE AND ADMINISTRATION

In most patients with mild to moderate anxiety and/or depression: 10 mg. to 25 mg. t.i.d. to start. A starting dosage of 10 mg. t.i.d. for a period of four days may reduce the initial drowsiness experienced by some patients, and may be tried in cases where drowsiness is clinically undesirable. Decrease or increase the dosage at appropriate intervals according to individual response. Usual optimum dosage is 75 mg. to 150 mg. per day.

In some patients with mild symptomatology or emotional symptoms accompanying organic disease, dosage as low as 25 mg. to 50 mg. per day has provided effective control.

In more severe anxiety and/or depression: 50 mg. t.i.d. may be required to start—if necessary, gradually increase to 300 mg. per day. Additional effectiveness is rarely obtained by exceeding 300 mg. per day.

Although optimal antidepressant response may not be evident for two to three weeks, antianxiety activity is rapidly apparent.

OVERDOSAGE

Symptoms—An increase of any of the reported adverse reactions, primarily excessive sedation and anticholinergic effects such as blurred vision and dry mouth. Other effects may be: pronounced tachycardia, hypotension and extrapyramidal symptoms.

Treatment—Essentially symptomatic; supportive therapy in the case of hypotension and excessive sedation.

HOW SUPPLIED

Each capsule contains doxepin, as the hydrochloride, 10 mg. (NDC 0018-0356), 25 mg. (NDC 0018-0357), and 50 mg. (NDC 0018-0358) capsules in bottles of 100 and 1000.

PENNWALT

Pennwalt Prescription Products

Put depression to rest

The h.s. schedule: provides symptomatic relief throughout the next day.

Because of its pharmacokinetic characteristics, Endep (amitriptyline HCl) Roche, provides the same clinical effect over a period of time when given as a single daily *h.s.* dose or as 1/3 the same dose given *t.i.d.*

The h.s. schedule: helps put side effects in their place.

100 mg Endep *h.s.* can provide relief of depression-induced insomnia. Once asleep, the patients are also less likely to notice anticholinergic side effects—such as dry mouth—which reach a peak hours after the *h.s.* dose.

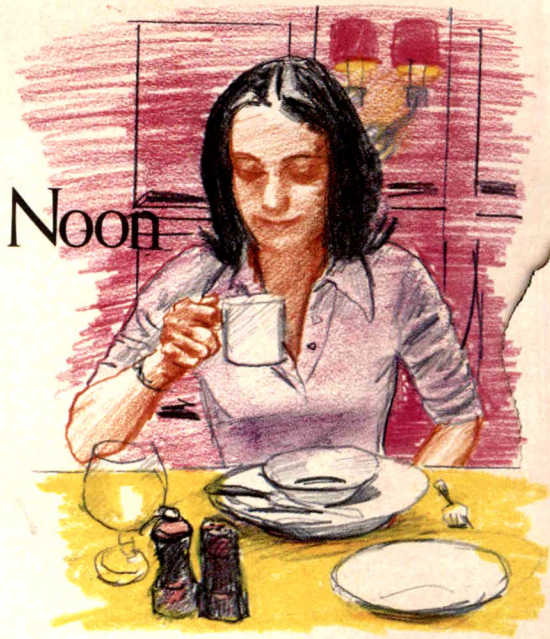
Midnight

Because the sedative effect may impair patients' performance during daytime, warn patients not to drive or operate dangerous machinery until the sedative potential has been clearly established.

The h.s. schedule: helps maximize patient compliance.

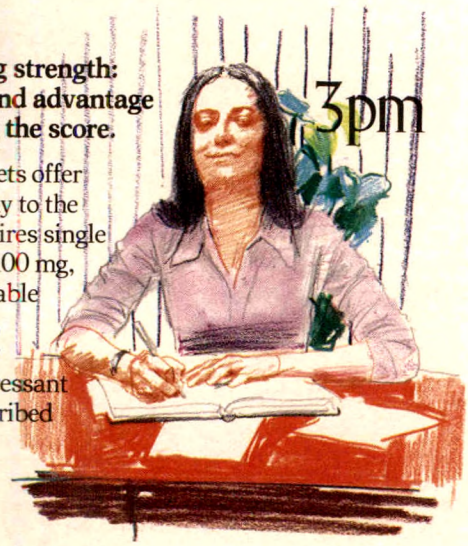
According to one investigation, only 40% of patients comply with a *t.i.d* drug schedule whereas 93% of patients comply with a one-dose-a-day schedule.[1] An *h.s.* schedule of Endep (amitriptyline HCl), therefore, should help you maximize patient compliance which, in turn, helps ensure prompt recovery.

ROCHE



all day long

The 100-mg strength: early signs of progress.



Many depressed patients with insomnia and anorexia begin to show improvement during the first week of Endep (amitriptyline HCl) therapy. Patients with symptoms of "neurotic" depression usually improve during the first week, whereas those with "psychotic" depression usually do not improve until the third week of therapy. However, adequate response may require up to 30 days in both types.

8am

Noon

3pm

The 100-mg strength: the economy and advantage of knowing the score.

- 100-mg tablets offer potential economy to the patient who requires single doses of 50 mg, 100 mg, or 150 mg. Available as scored tablets, Endep is the only tricyclic antidepressant that can be prescribed in half doses.

The 100-mg strength: emphasis on individualization of dosage.

The introduction of the 100-mg scored tablet brings to 5 the number of Endep dosage strengths now available as scored tablets: 10 mg, 25 mg, 50 mg, 75 mg, and 100 mg.

with new 100mg Endep®

amitriptyline HCl/Roche

Before prescribing, please consult complete product information, a summary of which appears on the following page.

Endep®
amitriptyline HCl/Roche

10 mg | 25 mg | 50 mg | 75 mg | Just released 100 mg

The only tricyclic antidepressant with scored tablets

- By relieving underlying depression Endep (amitriptyline HCl), in responsive patients, lifts mood and relieves symptoms such as anorexia, loss of interest, inability to concentrate, decreased libido or GI disturbances, often within three or four weeks after starting therapy.
- Endep usually relieves accompanying sleep disturbances, particularly early in the treatment regimen.
- All five dosage strengths are scored for greater flexibility and convenience in titration.
- The *h.s.* dosage minimizes skipped doses, maximizes patient acceptance and compliance.
- Specifying Endep assures quality plus potential economy.

Important Considerations

Should not be given concomitantly with an MAO inhibitor or within 2 weeks of its administration.

Patients should use caution in the performance of hazardous tasks such as operating machinery or driving a motor vehicle.

May enhance the effects of alcohol, barbiturates and other CNS depressants.

Not recommended for use during the acute recovery phase following myocardial infarction.

Patients with suicidal tendencies should not have easy access to large quantities of the drug.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: To relieve symptoms of depression (notably endogenous depressions) and depression accompanied by anxiety.

Contraindications: Known hypersensitivity. Do not use with monoamine oxidase (MAO) inhibitors or within at least 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Use not recommended during acute recovery phase after myocardial infarction.

Warnings: May block action of guanethidine or similar antihypertensives. Use with caution in patients with history of seizures, urinary retention, angle closure glaucoma, increased intraocular pressure. Closely supervise cardiovascular patients, hyperthyroid patients and those receiving thyroid medications. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, including amitriptyline HCl, especially in high doses. Myocardial infarction and stroke reported with use of this class of drugs.) May impair alertness; warn against hazardous occupations or driving a motor vehicle during therapy. Weigh possible benefits against hazards during pregnancy, the nursing period and in women of childbearing potential. Not recommended in children under 12.

Precautions: May exaggerate symptoms in schizophrenic and paranoid patients, or shift manic-depressives to manic stage; reduce dose or administer major tranquilizer concomitantly. Close supervision and careful dose adjustments required when given with anticholinergic or sympathomimetic agents. Exercise care in patients receiving large doses of ethchlorvynol; transient delirium reported with concomitant administration. May enhance effects of alcohol, barbiturates and other CNS depressants. Because of the possibility of suicide in depressed patients, do not permit easy access to large drug quantities in these patients. Because it may increase hazards of electroshock therapy, limit concomitant use to essential treatment. If possible, discontinue drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: This list includes a few adverse reactions not reported with this specific drug but requiring consideration because of similarities of tricyclic antidepressants. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, jaundice, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache and malaise. These are not indicative of addiction.

Dosage: Initiate at low levels; increase gradually, watching for signs of intolerance. As long as 30 days may elapse before adequate antidepressant effect develops; sedative effect may be noted earlier.

Initial Adult Dosage: Outpatients—25 mg *t.i.d.*; may be increased to 150 mg/day. Add increased drug to afternoon and/or bedtime doses. Alternate—50 to 100 mg *h.s.*, gradually increasing *h.s.* dose up to 150 mg/day. Hospitalized Patients—Up to 100 mg/day; increase gradually to 200 mg if necessary. A few patients may require 300 mg/day.

Adolescent and Elderly Patients: In general, 10 mg *t.i.d.* with 20 mg *h.s.* may be satisfactory for those who do not tolerate higher doses.

Maintenance Dosage: With symptomatic improvement, reduce dosage to lowest amount that gives relief, usually 25 mg *b.i.d.* to *q.i.d.*, or 10 mg *q.i.d.* Continue maintenance therapy 3 months or longer to avoid relapse.

Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. IV administration of 1 to 3 mg physostigmine salicylate reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestations and treatment.

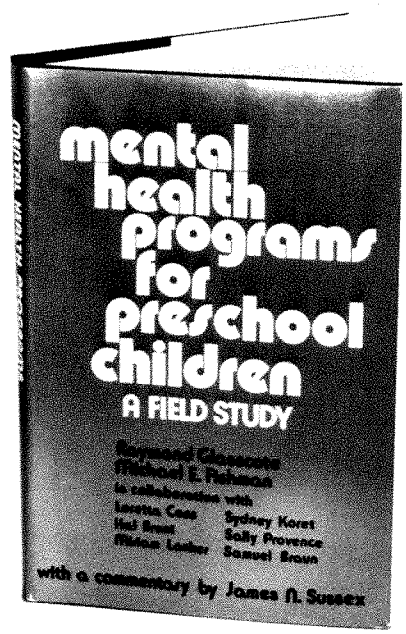
Supplied: 10-mg, 25-mg, 50-mg, 75-mg and 100-mg scored tablets—bottles of 100 and 500; Tel-E-Dose® packages of 100; Prescription Paks of 60 (10 mg, 25 mg and 50 mg) or 30 (75 mg and 100 mg), available singly and in trays of 10.

ROCHE
Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, New Jersey 07110

In depression... when biogenic amine deficits may exist

Indication: For relief of mental depression. **Contraindications:** Do not use MAO inhibitors concomitantly or within 2 weeks of the use of this drug. Hyperpyretic crises or severe convulsive seizures may occur with such combinations; potentiation of adverse reactions can be serious or even fatal. When substituting Pertofrane (desipramine HCl) in patients receiving an MAO inhibitor, allow an interval of at least 14 days. Initial dosage in such patients should be low and increases should be gradual and cautiously prescribed. The drug is contraindicated following recent myocardial infarction and in patients with a known hypersensitivity to tricyclic antidepressants. **Warnings:** Activation of psychosis may occasionally be observed in schizophrenic patients. Due to atropine-like effects and sympathomimetic potentiation, use only with the greatest care in patients with narrow-angle glaucoma or urethral or ureteral spasm. Do not use in patients with the following conditions unless the need outweighs the risk: severe coronary heart disease with EKG abnormalities, progressive heart failure, angina pectoris, paroxysmal tachycardia and active seizure disorder (may lower seizure threshold). This drug may block the action of the antihypertensive, guanethidine, and related adrenergic neuron-blocking agents. Hypertensive episodes have been observed during surgery. The concurrent use of other central nervous system drugs or alcohol may potentiate adverse effects. Since many such drugs may be used during surgery, desipramine should be discontinued prior to elective procedures. Caution patients on the possibility of impaired ability to operate a motor vehicle or dangerous machinery. Do not use in women who are or may become pregnant, or in children under 12 years of age, unless the clinical situation warrants the potential risk. Because of increased sensitivity to the drug, use lower than normal dosage in adolescent and geriatric patients. **Precautions:** Potentially suicidal patients require careful supervision and protective measures during therapy. Prescriptions should be limited to small quantities. Discontinuation of the drug may be necessary in the presence of increased agitation and anxiety shifting to hypomanic or manic excitement. Atropine-like effects may be more pronounced (e.g. paralytic ileus) in susceptible patients and in those receiving anticholinergic drugs (including antiparkinsonism agents). Prescribe cautiously in hyperthyroid patients and in those receiving thyroid medications; transient cardiac arrhythmias have occurred in rare instances. Periodic blood and liver studies should supplement careful clinical observations in all patients undergoing extended courses of therapy. **Adverse Reactions:** The following have been reported: *Nervous System:* dizziness, drowsiness, insomnia, headache, disturbed visual accommodation, tremor, unsteadiness, tinnitus, paresthesias, changes in EEG patterns, epileptiform seizures, mild extrapyramidal activity, falling and neuromuscular incoordination. A confusional state (with such symptoms as hallucinations and disorientation), particularly in older patients and at higher dosage, may require discontinuation of the drug. *Gastrointestinal Tract:* anorexia, dryness of the mouth, nausea, epigastric distress, constipation and diarrhea. *Skin:* skin rashes (including photosensitization), perspiration and flushing sensations. *Liver:* rare cases of transient jaundice (apparently of an obstructive nature) and liver damage. If jaundice or abnormalities in liver function tests occur, discontinue the drug and investigate. *Blood Elements:* bone-marrow depression, agranulocytosis, thrombocytopenia and purpura. If these occur, discontinue the drug. Transient eosinophilia has been observed. *Cardiovascular System:* orthostatic hypotension and tachycardia. Carefully supervise patients requiring concomitant vasodilating therapy, particularly during initial phases. *Genitourinary System:* urinary frequency or retention and impotence. *Endocrine System:* occasional hormonal effects, including gynecomastia, galactorrhea and breast enlargement, and decreased libido and estrogenic effect. *Sensitivity:* urticaria and rare instances of drug fever and cross-sensitivity with imipramine. **Dosage:** All patients except geriatric and adolescent: 50 mg. t.i.d. (150 mg. daily). Dosage may be increased up to 200 mg. daily. Geriatric and adolescent patients should usually be started with lower dosage (25 to 50 mg. daily) and may not tolerate higher doses. Dosage may be increased up to 100 mg. daily. Lower maintenance dosages should be continued for at least 2 months after obtaining a satisfactory response. Mild anxiety and agitation which may accompany depression usually remit as the depression responds. Occasionally, however, a sedative or tranquilizer may be indicated. **How Supplied:** 25 mg. capsules (pink), bottles of 100 and 1000. Also, 50 mg. capsules (maroon and pink), bottles of 100 and 1000.

Pertofrane®
(desipramine HCl NF)



to help restore neurochemical balance

USV Pharmaceutical Mfg. Corp.

A Timely New Book from The Joint Information Service

This latest Joint Information Service field study provides a concise, comprehensive overview of the complex matter of the very young American child and his mental health, and then describes in intimate detail seven unique programs for pre-school children with problems—from North Hollywood's Dubnoff Center, emphasizing education as its primary therapeutic modality, to Baltimore's Martin Luther King, Jr. Parent-Child Center, serving two housing projects, served by Johns Hopkins, and largely governed by its own people. All different in treatment approach and philosophy, the programs described are uniform in their dedication to innovation in improving service to the emotionally disturbed very young child, and, equally, to the emotional well being of all young children.

This thoughtful and perceptive description of what has been created by some of the best informed, most experienced and thoughtful specialists in mental health services for very young children should be welcome to all involved in the mental health of children and a casebook for those dealing with child and family mental health.

An articulate exposition of the immense problems and encouraging accomplishments in a particularly difficult area of endeavor . . . . Beyond their concern with the manifestly ill child, the authors intriguingly explore what may be needed to enhance the mental good health of all young children . . . . A significant contribution.

No default insurance

Tofranil-**PM**®
imipramine **pamoate**

Geigy

In depression

Daily Dosage Chart

1 h.s.

A major reason for drug defaulting is multiple daily dosage schedules.

Ayd* reports that 70 percent of patients default on a q.i.d. regimen; 60 percent on t.i.d.; 30 percent on b.i.d., and only 7 percent on a single daily dose.

A single daily capsule that provides a full day's medication would logically assure better therapeutic results.

Because one capsule lasts from bedtime to bedtime, Tofranil-**PM**® may markedly reduce the probability of missed doses.

After therapy is initiated with the 75-mg. capsule, the 150-mg. capsule is the dose level at which optimum response is usually obtained.

Please review the prescribing information summarized on the back of this page.

*Ayd, F.J., Jr. (Ed.): Int. Drug Ther. Newslett. 7(9/10):35-50 (Nov./Dec.) 1972.

Tofranil-PM®
imipramine pamoate

One capsule
lasts from bedtime
to bedtime.

Initial Dose

For Maintenance Therapy

Starting Dose	Usual Optimum Response Dose	A Full Range to Choose From*			
					
75 mg.	150 mg.	150 mg.	125 mg.	100 mg.	75 mg.

*Each capsule contains imipramine pamoate equivalent to 150, 125, 100 or 75 mg. imipramine hydrochloride.

Tofranil-PM®
brand of imipramine pamoate

Indications: For the relief of symptoms of depression. Endogenous depression is more likely to be alleviated than other depressive states.

Contraindications: The concomitant use of monoamine oxidase inhibiting compounds is contraindicated. Hyperpyretic crises or severe convulsive seizures may occur in patients receiving such combinations. The potentiation of adverse effects can be serious, or even fatal. When it is desired to substitute Tofranil-PM, brand of imipramine pamoate, in patients receiving a monoamine oxidase inhibitor, as long an interval should elapse as the clinical situation will allow, with a minimum of 14 days. Initial dosage should be low and increases should be gradual and cautiously prescribed. The drug is contraindicated during the acute recovery period after a myocardial infarction. Patients with a known hypersensitivity to this compound should not be given the drug. The possibility of cross-sensitivity to other dibenzazepine compounds should be kept in mind.

Warnings: *Usage in Pregnancy:* Safe use of imipramine during pregnancy and lactation has not been established; therefore, in administering the drug to pregnant patients, nursing mothers, or women of childbearing potential, the potential benefits must be weighed against the possible hazards. Animal reproduction studies have yielded inconclusive results. There have been clinical reports of congenital malformation associated with the use of this drug, but a causal relationship has not been confirmed.

Extreme caution should be used when this drug is given to:

—patients with cardiovascular disease because of the possibility of conduction defects, arrhythmias, myocardial infarction, strokes and tachycardia;
—patients with increased intraocular pressure, history of urinary retention, or history of narrow-angle glaucoma because of the drug's anticholinergic properties;
—hyperthyroid patients or those on thyroid medication because of the possibility of cardiovascular toxicity;
—patients with a history of seizure disorder because this drug has been shown to lower the seizure threshold;
—patients receiving guanethidine or similar agents since imipramine may block the pharmacologic effects of these drugs.

Since imipramine may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as operating an automobile or machinery, the patient should be cautioned accordingly.

Usage in Children: Tofranil-PM, brand of imipramine pamoate, should not be used in children of any age because of the increased potential for acute overdosage due to the high unit potency (75 mg., 100 mg., 125 mg. and 150 mg.). Each capsule contains imipramine pamoate equivalent to 75 mg., 100 mg., 125 mg. or 150 mg. imipramine hydrochloride.

Precautions: It should be kept in mind that the possibility of suicide in seriously depressed patients is inherent in the illness and may persist until significant remission occurs. Such patients should be carefully supervised during the early phase of treatment with Tofranil-PM, brand of imipramine pamoate, and may require hospitalization. Prescriptions should be written for the smallest amount feasible.

Hypomanic or manic episodes may occur, particularly in patients with cyclic disorders. Such reactions may necessitate discontinuation of the drug. If needed, Tofranil-PM, brand of imipramine pamoate, may be resumed in lower dosage when these episodes are relieved. Administration of a tranquilizer may be useful in controlling such episodes.

Prior to elective surgery, imipramine should be discontinued for as long as the clinical situation will allow.

An activation of the psychosis may occasionally be observed in schizophrenic patients and may require reduction of dosage and the addition of a phenothiazine.

In occasional susceptible patients or in those receiving anticholinergic drugs (including antiparkinsonism agents) in addition, the atropine-like effects may become more pronounced (e.g., paralytic ileus). Close supervision and careful adjustment of dosage is required when this drug is administered concomitantly with anticholinergic or sympathomimetic drugs.

Avoid the use of preparations, such as decongestants and local anesthetics, which contain any sympathomimetic amine (e.g., adrenalin, noradrenalin), since it has been reported that tricyclic antidepressants can potentiate the effects of catecholamines.

Patients should be warned that the concomitant use of alcoholic beverages may be associated with exaggerated effects.

Both elevation and lowering of blood sugar levels have been reported.

Concurrent administration of imipramine with electroshock therapy may increase the hazards; such treatment should be limited to those patients for whom it is essential, since there is limited clinical experience.

Adverse Reactions: Note: Although the listing which follows includes a few adverse reactions which have not been reported with this specific drug, the pharmacological similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when imipramine is administered.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke, falls.

Psychiatric: Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurological: Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alterations in EEG patterns; tinnitus.

Anticholinergic: Dry mouth, and, rarely, associated sublingual adenitis; blurred vision, disturbances of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

Allergic: Skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight); edema (general or of face and tongue); drug fever; cross-sensitivity with desipramine.

Hematologic: Bone marrow depression including agranulocytosis; eosinophilia; purpura; thrombocytopenia. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathological neutrophil depression.

Gastrointestinal: Nausea and vomiting, anorexia, epigastric distress, diarrhea; peculiar taste, stomatitis, abdominal cramps, black tongue.

Endocrine: Gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood sugar levels.

Other: Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency; drowsiness, dizziness, weakness and fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: Though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache and malaise.

Dosage and Administration: In adult outpatients, therapy should be initiated on a once-a-day basis with 75 mg./day. This may be increased to 150 mg./day which is the dose level which usually obtains optimum response. If necessary, dosage may be increased to 200 mg./day. Dosage should be modified as necessary by clinical response and any evidence of intolerance. Daily dosage may be given at bedtime, or in some patients in divided daily doses.

Hospitalized patients should be started on a once-a-day basis with 100-150 mg./day and may be increased to 200 mg./day. Dosage should be increased to 250-300 mg./day if there is no response after two weeks.

Following remission, maintenance medication may be required for a longer period of time at the lowest dose that will maintain remission. The usual adult maintenance dosage is 75-150 mg./day on a once-a-day basis, preferably at bedtime.

In adolescent and geriatric patients, capsules of Tofranil-PM, brand of imipramine pamoate, may be used when total daily dosage is established at 75 mg. or higher. It is generally unnecessary to exceed 100 mg./day in these patients. This dosage may be given once a day at bedtime or, if needed, in divided daily doses.

How Supplied: Tofranil-PM, brand of imipramine pamoate: Capsules of 75, 100, 125 and 150 mg. (Each capsule contains imipramine pamoate equivalent to 75, 100, 125 or 150 mg. of imipramine hydrochloride.)

MANAGING MADNESS

The Case Against Civil Commitment

Kent S. Miller, Community Mental Health Center, Florida State University

"Civil commitment for mental illness is wrong," says the author. Getting at the real story behind the headline-making controversies over involuntary hospitalization (and the public backlash against the release of mental patients to the community), Miller uses actual case histories to document a startlingly strong argument against civil commitment.

"Kent Miller's case against civil commitment is compelling and convincing. He marshals his data well and his arguments are clear and persuasive. His book should be read and studied by legislators, judges, lawyers, social welfare professionals, and all do-gooders who believe that good intentions make for good social policy." — David J. Rothman, author of *The Discovery of the Asylum*

Examines special psychological needs

THE HOSPITALIZED ADOLESCENT

A Guide to Managing the Ill and Injured Youth

Adele D. Hofmann, M.D., New York University Medical Center; R.D. Becker, Ph.D., Hadassah University Hospital; and H. Paul Gabriel, M.D., New York University Medical Center

Foreword by Anna Freud

This is the first book to explore the special emotional and developmental needs of the hospitalized adolescent. It provides a comprehensive introduction to the concepts of adolescent psychiatry; step-by-step guidelines for setting up and operating an adolescent ward; and a practical discussion of particularly difficult problems such as devastating injury and terminal illness. It also deals with the legal and ethical aspects of a minor's rights of privacy, confidentiality and consent.

320 pages $14.95

A valuable practice guide for those working with troubled couples

MARITAL COMMUNICATION AND DECISION MAKING

Analysis, Assessment and Change

Edwin J. Thomas, University of Michigan

Outlines a concrete, systematic approach for solving problems involving communication and decision making between marital partners. To illustrate these methods, some fifty specific communication and decision-making problems are analyzed through actual case examples, including the recorded dialogue of married couples in conflict.

224 pages $12.95

An invaluable aid for anyone who works with groups

THE INTENSIVE GROUP EXPERIENCE

Edited by Max Rosenbaum, Adelphi University and the National Academy of Professional Psychologists, and Alvin Snadowsky, Brooklyn College

With original contributions by Martin Lakin, Burton Giges, Edward Rosenfeld, David Hays, Yael Danieli and Rosabeth Moss Kanter

This is the most comprehensive treatment of group dynamics available, covering therapy groups, sensitivity groups, human relations training, and communes. Each type of group is explored through an historical review, an examination of techniques, and an analysis of current trends. Research findings are cited to assess the effectiveness of each type of group experience, giving the reader a perspective on those techniques that have survived and those that failed.

NEW ORAL CONCENTRATE

Loxitane® C

LOXAPINE HYDROCHLORIDE

Lederle

25 mg base/ml* In bottles of 4 fl. oz.

Effectiveness – the only clue that it's there

DESCRIPTION

*Each ml contains the equivalent of 25 mg loxapine base as the HCl.

LOXITANE *loxapine*, a dibenzoxazepine compound represents a new subclass of tricyclic antipsychotic agent, chemically distinct from the thioxanthenes, butyrophenones, and phenothiazines. Chemically, it is 2-chloro-11-(4-methyl-1-piperazinyl)dibenz[b,f][1,4]oxazepine. It is present in the oral concentrate primarily as the HCl.

ACTIONS

Pharmacologically, loxapine is a tranquilizer for which the exact mode of action has not been established. However, changes in the level of excitability of subcortical inhibitory areas have been observed in several animal species in association with such manifestations of tranquilization as calming effects and suppression of aggressive behavior.

In normal human volunteers, signs of sedation were seen within 20 to 30 minutes after administration, were most pronounced within 1 1/2 to 3 hours, and lasted through 12 hours. Similar timing of primary pharmacologic effects was seen in animals.

Absorption of loxapine following oral or parenteral administration is virtually complete. The drug is removed rapidly from the plasma and distributed in tissues. Animal studies suggest an initial preferential distribution in lungs, brain, spleen, heart, and kidney. Loxapine is metabolized extensively and is excreted mainly in the first 24 hours. Metabolites are excreted in the urine in the form of conjugates and in the feces unconjugated.

INDICATIONS

LOXITANE C *loxapine hydrochloride* is indicated for the manifestations of schizophrenia.

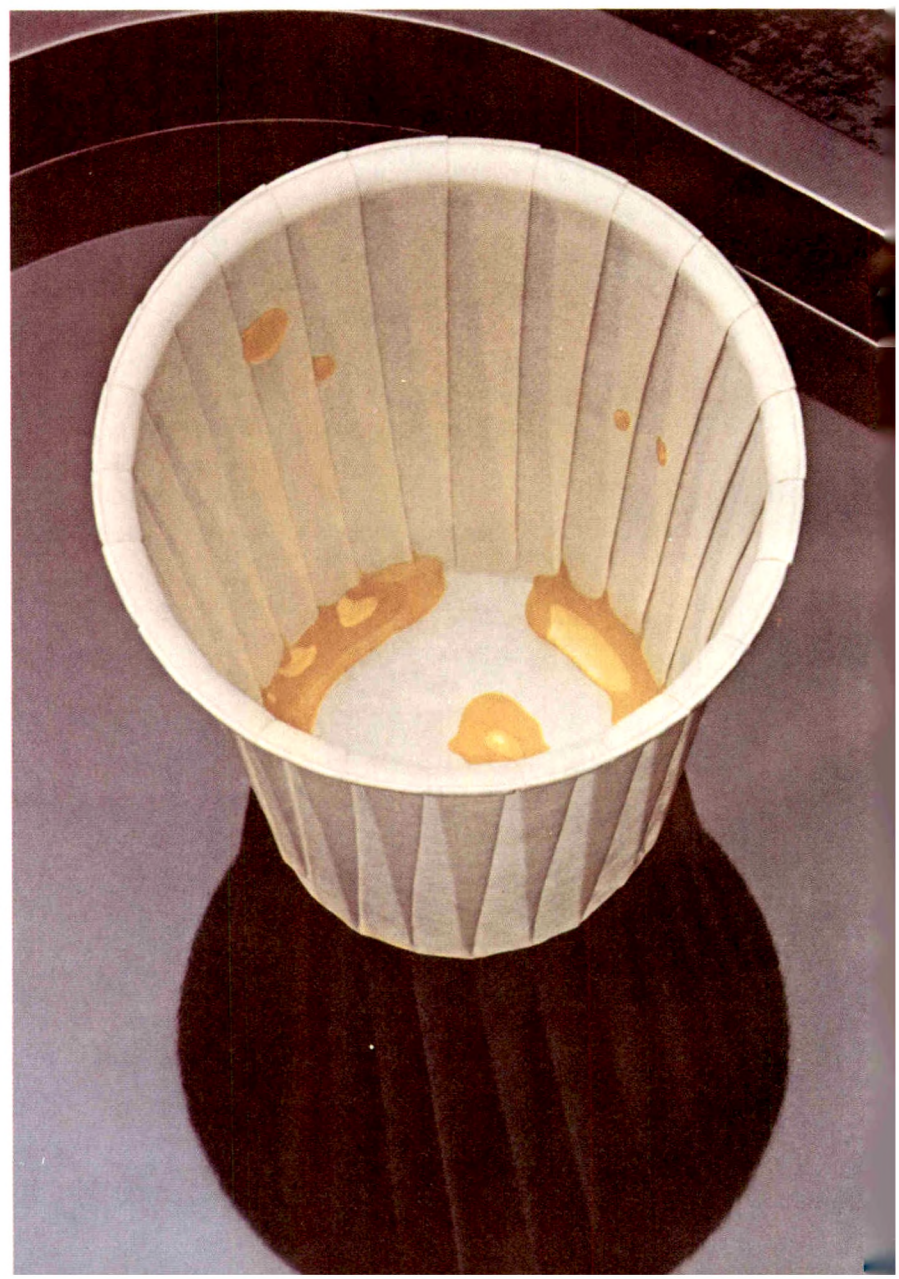
LOXITANE has not been shown effective in the management of behavioral complications in patients with mental retardation.

CONTRAINDICATIONS

LOXITANE is contraindicated in comatose or severe drug-induced depressed states (alcohol, barbiturates, narcotics, etc.)

LOXITANE is contraindicated in individuals with known hypersensitivity to the drug.

WARNINGS



Usage in Pregnancy: Safe use of LOXITANE C *loxapine hydrochloride* during pregnancy or lactation has not been established; therefore, its use in pregnancy, in nursing mothers, or in women of childbearing potential requires that the benefits of treatment be weighed against the possible risks to mother and child. No embryotoxicity or teratology was observed in studies in rats, rabbits or dogs, although with the exception of one rabbit study, the highest dosage was only two times the maximum recommended human dose and in some studies they were below this dose. Perinatal studies have shown renal papillary abnormalities in offspring of rats treated from mid-pregnancy with doses of 0.6 and 1.8 mg/kg, doses which approximate the usual human dose but which are considerably below the maximum recommended human dose.

Usage in Children: Studies have not been performed in children; therefore this drug is not recommended for use in children below the age of 16.

LOXITANE C *loxapine hydrochloride*, like other tranquilizers, may impair mental and/or physical abilities, especially during the first few days of therapy. Therefore, ambulatory patients should be warned about activities requiring alertness (e.g. operating vehicles or machinery), and about concomitant use of alcohol and other CNS depressants.

PRECAUTIONS

LOXITANE should be used with extreme caution in patients with a history of convulsive disorders since it lowers the convulsive threshold. Seizures have been reported in epileptic patients receiving LOXITANE at antipsychotic dose levels, and may occur even with maintenance of routine anticonvulsant drug therapy.

Tasteless in orange, grapefruit and pineapple juices

Highly acceptable to patients who prefer medication in fruit juices, and a logical alternative to tablets or capsules when good patient management depends on uninterrupted treatment. LOXITANE C Oral Concentrate is as easy to take as the fruit juice in which it may be administered.

Same efficacy as LOXITANE Capsules

Efficacy that speaks for itself with substantial reduction in the symptoms of schizophrenia.

Same favorable side effects profile as with LOXITANE Capsules[1]

In 31 studies involving 469 schizophrenic patients, certain favorable trends were exhibited in the LOXITANE side effects profile; these require further tests and broader clinical experience for confirmation.[1]

Same daily dosage schedule as with LOXITANE Capsules

The dropper is calibrated to conform to usual dosage requirements.

Loxapine has an antiemetic effect in animals. Since this effect may also occur in man, loxapine may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

LOXITANE should be used with caution in patients with cardiovascular disease. Increased pulse rates have been reported in the majority of patients receiving antipsychotic doses; transient hypotension has been reported. In the presence of severe hypotension requiring vasopressor therapy, the preferred drugs may be norepinephrine or angiotensin. Usual doses of epinephrine may be ineffective because of inhibition of its vasopressor effect by loxapine.

The possibility of ocular toxicity from loxapine cannot be excluded at this time. Therefore, careful observation should be made for pigmentary retinopathy and lenticular pigmentation since these have been observed in some patients receiving certain other antipsychotic drugs for prolonged periods.

Because of possible anticholinergic action, the drug should be used cautiously in patients with glaucoma or a tendency to urinary retention, particularly with concomitant administration of anticholinergic-type antiparkinson medication.

ADVERSE REACTIONS

CNS Effects: Manifestations of adverse effects on the central nervous system, other than extrapyramidal effects, have been seen infrequently. Drowsiness, usually mild, may occur at the beginning of therapy or when dosage is increased.

It usually subsides with continued LOXITANE therapy. The incidence of sedation has been less than that of certain aliphatic phenothiazines and slightly more than the piperazine phenothiazines. Dizziness, faintness, staggering gait, muscle twitching, weakness, and confusional states have been reported.

Extrapyramidal Reactions—Neuromuscular (extrapyramidal) reactions during the administration of LOXITANE C *loxapine hydrochloride* have been reported frequently, often during the first few days of treatment. In most patients, these reactions involved Parkinson-like symptoms such as tremor, rigidity, excessive salivation, and masked facies. Akathisia (motor restlessness) also has been reported relatively frequently. These symptoms are usually not severe and can be controlled by reduction of LOXITANE dosage or by administration of antiparkinson drugs in usual dosage. Dystonic and dyskinetic reactions have occurred less frequently, but may be more severe. Dystonias include spasms of muscles of the neck and face, tongue protrusion, and oculogyric movement. Dyskinetic reaction has been described in the form of choreo-athetoid movements. These reactions sometimes require reduction or temporary withdrawal of LOXITANE dosage in addition to appropriate counteractive drugs.

Persistent Tardive Dyskinesia—As with all antipsychotic agents, tardive dyskinesia may appear in some patients on long-term therapy or may appear after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movement of the tongue, face, mouth, or jaw (eg, protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia; antiparkinson agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been suggested that fine vermicular movements of the tongue may be an early sign of the syndrome, and if the medication is stopped at that time the syndrome may not develop.

Cardiovascular Effects: Tachycardia, hypotension, hypertension, lightheadedness, and syncope have been reported.

A few cases of ECG changes similar to those seen with phenothiazines have been reported. It is not known whether these were related to loxapine administration.

Skin: Dermatitis, edema (puffiness of face), pruritus, and seborrhea have been reported with loxapine. The possibility of photosensivitity and/or phototoxicity occurring has not been excluded; skin rashes of uncertain etiology have been observed in a few patients during hot summer months.

Endocrine Effects: No endocrine abnormalities have been reported.

Anticholinergic Effects: Dry mouth, nasal congestion, constipation, and blurred vision have occurred; these are more likely to occur with concomitant use of antiparkinson agents.

Other Adverse Reactions: Nausea, vomiting, weight gain, weight loss, dyspnea, ptosis, hyperpyrexia, flushed facies, headache, paresthesia, and polydipsia have been reported in some patients.

DOSAGE AND ADMINISTRATION

LOXITANE C *loxapine hydrochloride* is administered orally usually in divided doses two to four times a day. Daily dosage (in terms of base equivalents) should be adjusted to the individual patient's needs as assessed by the severity of symptoms and previous history of response to antipsychotic drugs. Initial dosage of 10 mg twice daily is recommended, although in severely disturbed patients initial dosage up to a total of 50 mg daily may be desirable. Dosage should then be increased fairly rapidly over the first seven to ten days until there is effective control of psychotic symptoms. The usual therapeutic and maintenance range is 60 mg to 100 mg daily. However, as with other antipsychotic drugs, some patients respond to lower dosage and others require higher dosage for optimal benefit. Daily dosage higher than 250 mg is not recommended. For maintenance therapy, dosage should be reduced to the lowest level compatible with symptom control; many patients have been maintained satisfactorily at dosages in the range of 20 mg to 60 mg daily.

LOXITANE C Oral Concentrate should be mixed with orange or grapefruit juice shortly before administration.

Use only the enclosed calibrated (10 mg, 15 mg, 20 mg, 25 mg) dropper for dosage.

HOW SUPPLIED

LOXITANE C *loxapine hydrochloride* is supplied in bottles of 4 fl. oz. (120 ml) with calibrated dropper. Each ml contains the equivalent of 25 mg loxapine base as the HCl. Rev 4/76

1. See LOXITANE C package insert for detailed information concerning side effects, contraindications, warnings and precautions.

If you think adjunctive antianxiety therapy is indicated...

Consider Serax® (oxazepam). It has been proved useful when anxiety and tension aren't responsive to simple reassurance and counsel.

Serax has been found valuable, particularly in the older patient, in the management and control of clinically significant anxiety, tension, agitation and irritability. It may also be useful where anxiety accompanies an underlying organic disorder.

Of special importance to elderly patients, Serax may be taken generally without fear of serious side effects.* Its dosage flexibility† generally permits adjustment to individual patient needs, making Serax a convenient adjunct to your therapy in the older patient.

Special care must, of course, be taken in prescribing antianxiety agents for elderly patients, especially where cardiac complications might ensue from a drop in blood pressure. And careful attention must be paid to dosage recommendations and follow-up observation.

*See following important information.
†See package circular for full prescribing information.

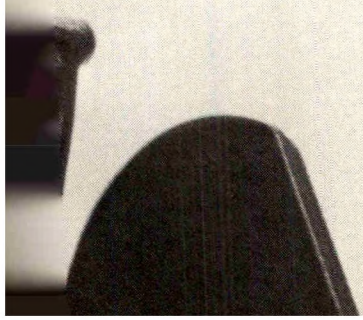
In Brief:

Indications: Oxazepam is indicated for the management and control of anxiety, tension, agitation, irritability and related symptoms. Such symptoms are commonly seen in patients with a diagnosis of psychoneurotic reaction, psychophysiological reaction, personality disorder, or in patients with underlying organic disease. Anxiety associated with depression is also responsive to oxazepam therapy. This product has been found particularly useful in the management of anxiety, tension, agitation and irritability in older patients. Alcoholics with acute tremulousness, inebriation or with anxiety associated with alcohol withdrawal are responsive to therapy.

Contraindications: History of previous hypersensitivity to oxazepam. Oxazepam is not indicated in psychoses.

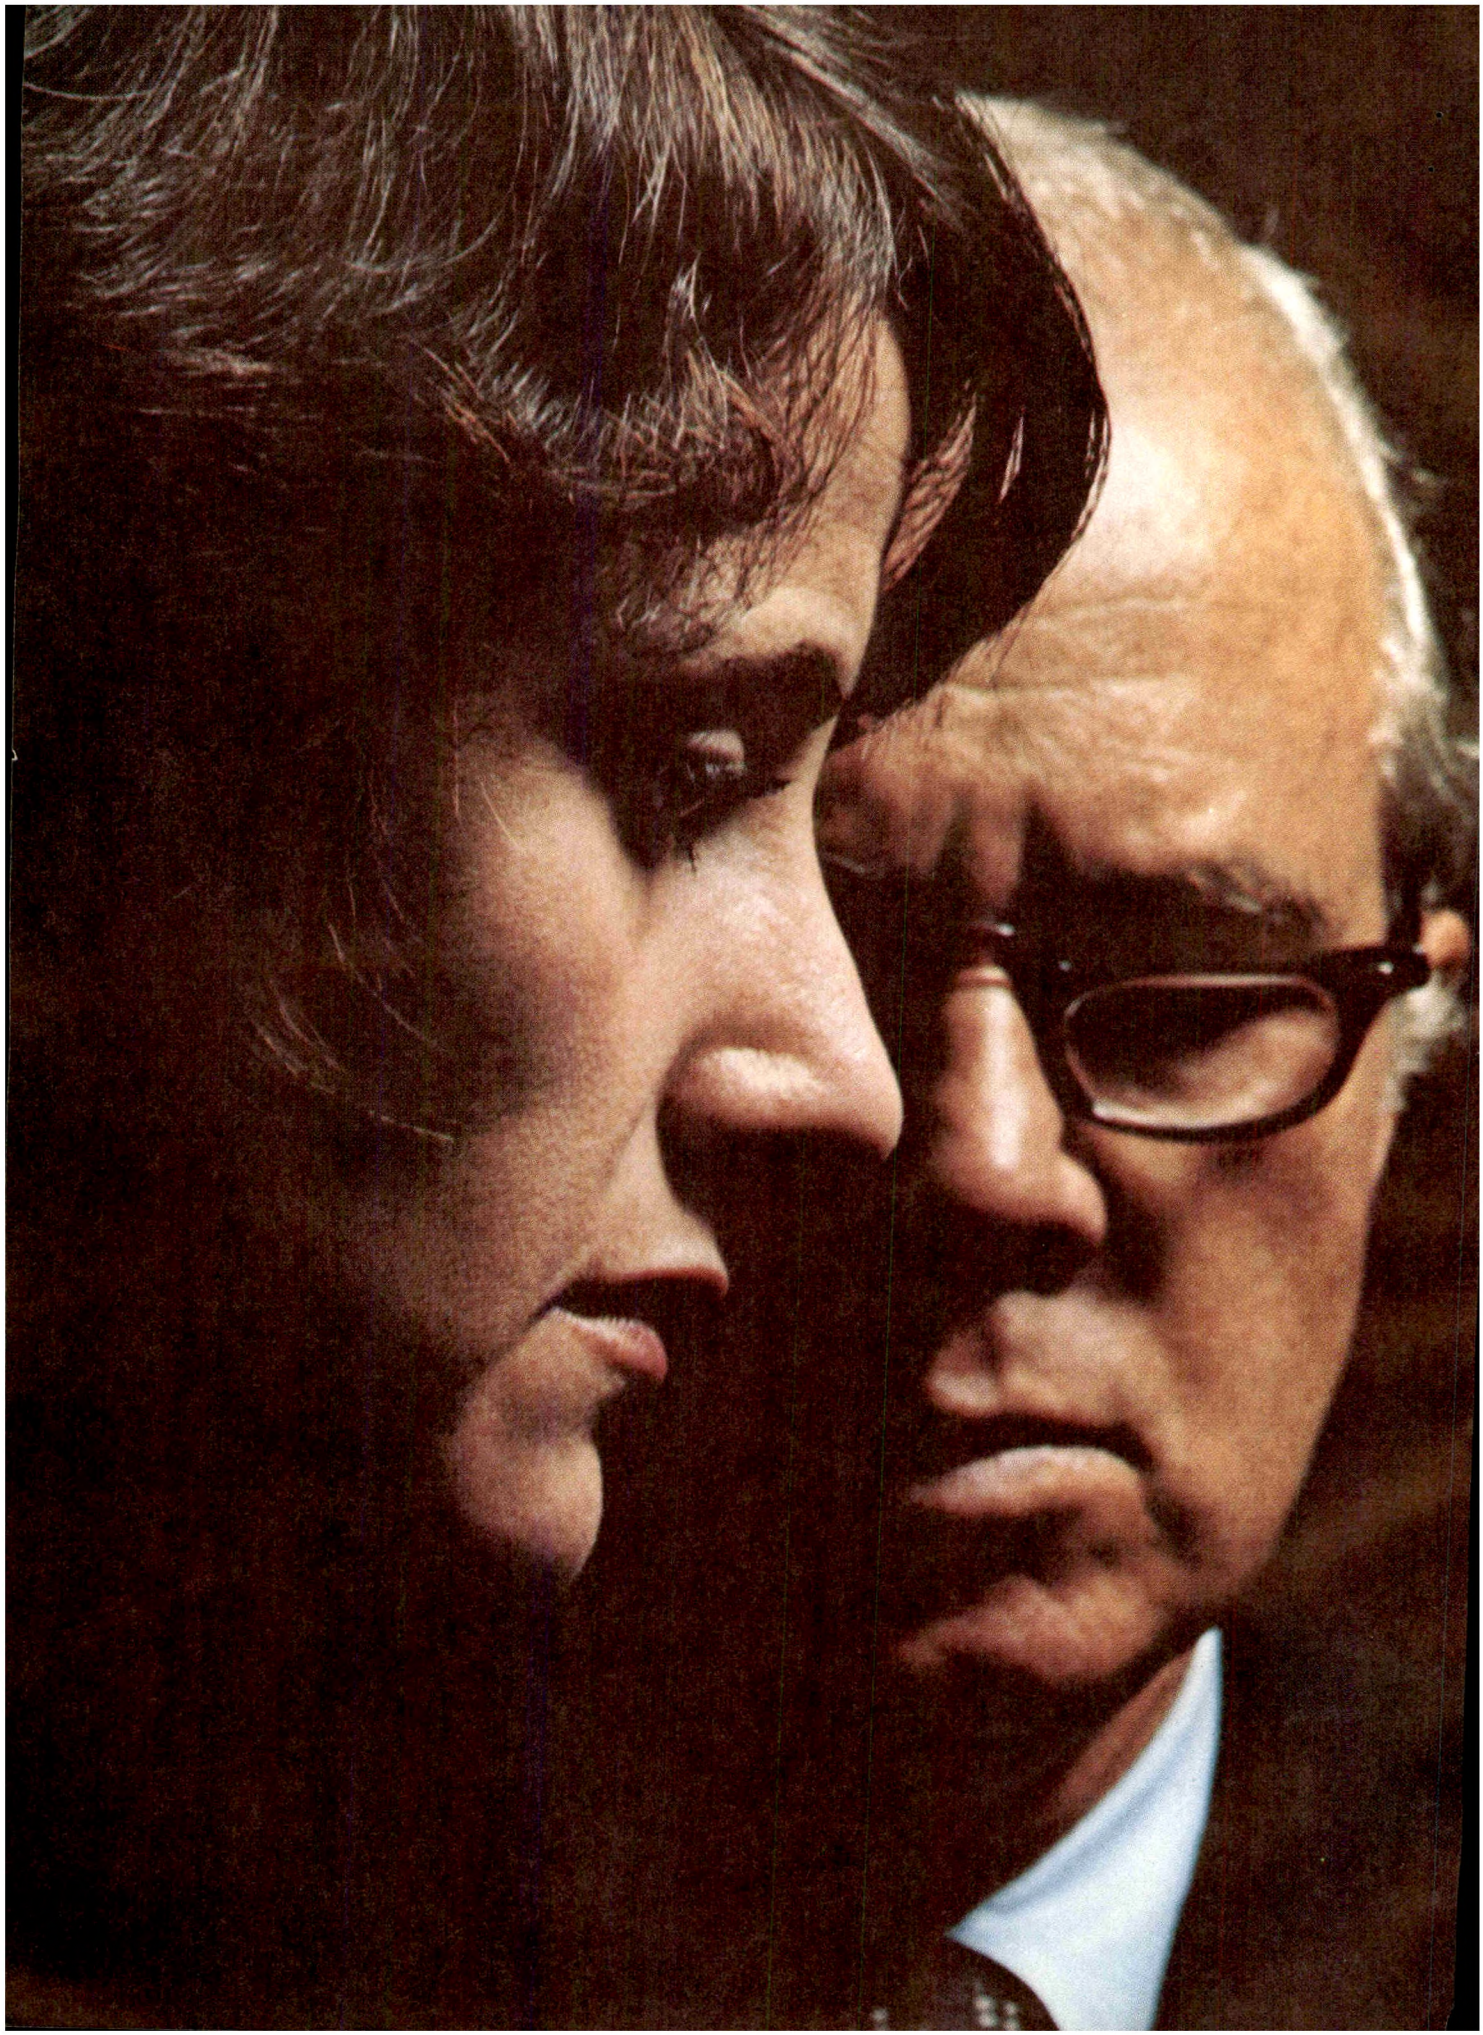
Warning: Use in Pregnancy:

An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. Serax, a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug.



Precautions: Hypotensive reactions are rare, but use with caution where cardiac complications could ensue from a fall in blood pressure, especially in the elderly. Withdrawal symptoms upon discontinuation have been noted in some patients exhibiting drug dependence through chronic overdose. Carefully supervise dose and amounts prescribed, especially for patients prone to self-overdose; excessive, prolonged use in susceptible patients (alcoholics, ex-addicts, etc.) may result in dependence or habituation. Reduce dosage gradually after prolonged excessive dosage to avoid possible epileptiform seizures. Withdrawal symptoms following abrupt discontinuance are similar to those seen with barbiturates. Caution patients against driving or operating machinery until absence of drowsiness or dizziness is ascertained. Warn patients of possible reduction in alcohol tolerance. Not indicated in children under 6 years; absolute dosage for 6- to 12-year-olds not established.

Adverse Reactions: Therapy-interrupting side effects are rare. Transient mild drowsiness is common initially; if persistent, reduce dosage. Dizziness, vertigo and headache have also occurred infrequently; syncope, rarely. Mild paradoxical reactions (excitement, stimulation of affect) are reported in psychiatric patients. Minor diffuse rashes (morbilliform, urticarial and maculopapular) are rare. Nausea, lethargy, edema, slurred speech, tremor and altered libido are rare and generally controllable by dosage reduction. Although rare, leukopenia and hepatic dysfunction including jaundice have been reported during therapy. Periodic blood counts and liver function tests are advised. Ataxia, reported rarely, does not appear related to dose or age. These side reactions, noted with related compounds, are not yet reported: paradoxical excitation with severe rage reactions, hallucinations, menstrual irregularities, change in EEG pattern, blood dyscrasias (including agranulocytosis), blurred vision, diplopia, incontinence, stupor, disorientation, fever and euphoria.



Availability: Capsules of 10, 15 and 30 mg. oxazepam; tablets of 15 mg. oxazepam.

In clinically significant anxiety

Serax®
(oxazepam)

Wyeth Laboratories · Philadelphia, Pa. 19101

The TRIAVIL® Potential in the management of moderate to severe anxiety with depression

When time and talk are not enough...
The therapist is the primary catalyst for change in the psychotherapeutic relationship. However, when patients suffer from moderate to severe anxiety with depression, there are situations when TRIAVIL can often be a useful adjunct.

...TRIAVIL may help
There are three important benefits you may expect when TRIAVIL is part of the treatment program: (1) When symptoms of moderate to severe anxiety or agitation with depression are relieved, the patient may become more accessible and cooperative. (2) As somatic manifestations are controlled, attention may be focused on underlying causative factors. (3) Symptomatic relief may enable the patient to function more effectively in his daily life while your work with the patient progresses.

Tablets TRIAVIL are available in four different combinations affording flexibility and individualized dosage adjustment. Since it is simpler to remember to take one tablet rather than several (particularly in multiple daily doses), your patients on TRIAVIL will be more likely to take proper doses of the medication.

TRIAVIL is contraindicated in CNS depression from drugs; in the presence of evidence of bone marrow depression; and in patients hypersensitive to phenothiazines or amitriptyline. It should not be used during the acute recovery phase following myocardial infarction or in patients who have received an MAOI within two weeks. Patients with cardiovascular disorders should be watched closely. Not recommended in children or during pregnancy. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol. Antiemetic effect may obscure toxicity due to other drugs or mask other disorders. Since suicide is a possibility in any depressive illness, patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

For a brief summary of prescribing information, please turn to the following page.

when patients exhibit moderate to marked anxiety or agitation with symptoms of depression

TRIAVIL® **containing perphenazine and amitriptyline HCl**

a tranquilizer-antidepressant

for highly effective relief of depression with moderate anxiety

TRIAVIL®

containing perphenazine and amitriptyline HCl a tranquilizer-antidepressant

Available:

TRIAVIL® 2-25: Each tablet contains 2 mg perphenazine and 25 mg amitriptyline HCl

TRIAVIL® 2-10: Each tablet contains 2 mg perphenazine and 10 mg amitriptyline HCl

TRIAVIL® 4-25: Each tablet contains 4 mg perphenazine and 25 mg amitriptyline HCl

TRIAVIL® 4-10: Each tablet contains 4 mg perphenazine and 10 mg amitriptyline HCl

INITIAL THERAPY FOR MANY PATIENTS
TRIAVIL® 2-25 (or TRIAVIL® 4-25) t.i.d. or q.i.d.

FOR FLEXIBILITY IN ADJUSTING MAINTENANCE THERAPY
TRIAVIL® 2-10 (or TRIAVIL® 4-10)

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, alcohol, narcotics, analgesics, antihistamines); bone marrow depression; known hypersensitivity to phenothiazines or amitriptyline. Do not give concomitantly with MAOI drugs because hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. Allow minimum of 14 days between therapies, then initiate therapy with TRIAVIL cautiously, with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction.

WARNINGS: TRIAVIL should not be given with guanethidine or similarly acting compounds. Use cautiously in patients with history of urinary retention, angle-closure glaucoma, increased intraocular pressure, or convulsive disorders. In patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, particularly in high doses, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. Caution patients performing hazardous tasks, such as operating machinery or driving motor vehicles, that drug may impair mental and/or physical abilities. Not recommended in children or during pregnancy.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.

Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of untoward actions is greater with high doses. Closely supervise with any dosage. The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction. A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.

If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine. Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides.

Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant. Patients with paranoid symptomatology may have an exaggeration of such symptoms. The tranquilizing effect of TRIAVIL seems to reduce the likelihood of this effect. When amitriptyline HCl is given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. Paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs.

Caution is advised if patients receive large doses of ethchlorvynol concurrently. Transient delirium has been reported in patients who were treated with 1 g of ethchlorvynol and 75-150 mg of amitriptyline HCl.

Amitriptyline HCl may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.

Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards associated with such therapy. Such treatment should be limited to patients for whom it is essential. Discontinue several days before elective surgery if possible. Elevation and lowering of blood sugar levels have both been reported. Use with caution in patients with impaired liver function.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.

Perphenazine: Side effects may be any of those reported with phenothiazine drugs: extrapyramidal symptoms (opisthotonus, oculogyric crisis, hyperreflexia, dystonia, akathisia, acute dyskinesia, ataxia, parkinsonism) can usually be controlled by the concomitant use of effective antiparkinsonian drugs and/or by reduction in dosage, but sometimes persist after discontinuation of the phenothiazine.

Tardive dyskinesia may appear in some patients on long-term therapy or may occur after drug therapy with phenothiazines and related agents has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. Symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Involuntary movements of the extremities sometimes occur. There is no known treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms. It is advised that all antipsychotic agents be discontinued if the above symptoms appear. If treatment is reinstituted, or dosage of the particular drug increased, or another drug substituted, the syndrome may be masked. It has been suggested that fine vermicular movements of the tongue may be an early sign of the syndrome, and that the full-blown syndrome may not develop if medication is stopped when lingual vermiculation appears.

Other side effects are skin disorders (photosensitivity, itching, erythema, urticaria, eczema, up to exfoliative dermatitis); other allergic reactions (asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions); peripheral edema; reversed epinephrine effect; hyperglycemia; endocrine disturbances (lactation, galactorrhea, gynecomastia, disturbances of menstrual cycle); altered cerebrospinal fluid proteins; paradoxical excitement; hypertension, hypotension, tachycardia, and ECG abnormalities (quinidine-like effect); reactivation of psychotic processes; catatonic-like states; autonomic reactions, such as dry mouth or salivation, headache, anorexia, nausea, vomiting, constipation, obstipation, urinary frequency or incontinence, blurred vision, nasal congestion, and a change in pulse rate; hypnotic effects; pigmentary retinopathy; corneal and lenticular pigmentation; occasional lassitude, muscle weakness, mild insomnia. Other adverse reactions reported with various phenothiazine compounds include blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosinophilia); liver damage (jaundice, biliary stasis); grand mal convulsions; cerebral edema; polyphagia; photophobia; skin pigmentation; and failure of ejaculation.

Amitriptyline: Note: Listing includes a few reactions not reported for this drug, but which have occurred with other pharmacologically similar tricyclic antidepressant drugs. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpitation; myocardial infarction; arrhythmias; heart block; stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth; blurred vision; disturbance of accommodation; constipation; paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic:* Skin rash; urticaria; photosensitization; edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastric distress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; parotid swelling; black tongue. Rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido; elevated or lowered blood sugar levels. *Other:* Dizziness; weakness; fatigue; headache; weight gain or loss; increased perspiration; urinary frequency; mydriasis; drowsiness; alopecia. *Withdrawal Symptoms:* Abrupt cessation after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

OVERDOSAGE: All patients suspected of having taken an overdosage should be admitted to a hospital as soon as possible. Treatment is symptomatic and supportive. However, the intravenous administration of 1–3 mg of physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage of physostigmine should be repeated as required particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine. On this basis, in severe overdosage with perphenazine-amitriptyline combinations, symptomatic treatment of central anticholinergic effects with physostigmine salicylate should be considered.

The vulnerable ages

The first epileptic seizure is most likely to occur during early childhood and at the onset of puberty

About 9 out of 10 epileptics experience their first seizure before the age of 20—with the highest incidence between 5 and 7, when children start school, and at the onset of puberty, a time of physiological and psychic turmoil.[1] The most common type, grand mal, occurs in approximately 75% of epileptic children,[1] and more than 50% of patients who suffer initially from petit mal develop grand mal seizures before they reach the age of 16.[2]

Mysoline (primidone) for control of grand mal, psychomotor and focal epilepsy

At the onset and afterwards — used alone or as concomitant therapy, MYSOLINE may reduce the frequency and severity of major motor seizures—or even eliminate them. *Excellent* for control of grand mal. Valuable for control of psychomotor[1,3,4] and focal epilepsy as well.[5]

Add Mysoline when control with other anticonvulsants is inadequate — As concomitant therapy, MYSOLINE can improve seizure control in grand mal and psychomotor epilepsy. The combined use of phenobarbital, diphenylhydantoin, and MYSOLINE may have additive anticonvulsant effects without additive side effects.[6]

Change to Mysoline when other anticonvulsants fail — A changeover to MYSOLINE is frequently warranted when other anticonvulsants must be discontinued because of important side effects, or when grand mal seizures are refractory to phenobarbital, with or without diphenylhydantoin.[7]

Mysoline® (primidone)

may be the start of a better life for the epileptic

initial and maintenance therapy for
grand mal, psychomotor and focal epilepsy

BRIEF SUMMARY
(For full prescribing information, see package circular.)

MYSOLINE® Brand of PRIMIDONE
Anticonvulsant

ACTIONS: MYSOLINE acts on the central nervous system to raise seizure threshold or alter seizure pattern. The mechanism(s) of action of anticonvulsant drugs is not known.

Primidone has anticonvulsant activity *per se*. In addition, its two metabolites possess anticonvulsant qualities. The major metabolite is phenylethylmalonamide (PEMA); the other is phenobarbital. In addition to its own anticonvulsant potential, PEMA potentiates phenobarbital.

INDICATIONS: MYSOLINE, either alone or used concomitantly with other anticonvulsants, is indicated in the control of grand mal, psychomotor, and focal epileptic seizures. It may control grand mal seizures refractory to other anticonvulsant therapy.

CONTRAINDICATIONS: Primidone is contraindicated in: 1) patients with porphyria and 2) patients who are hypersensitive to phenobarbital (see ACTIONS).

WARNINGS: The abrupt withdrawal of antiepileptic medication may precipitate status epilepticus.

The therapeutic efficacy of a dosage regimen takes several days before it can be assessed.

Use in pregnancy: Recent reports strongly suggest an association between the use of anticonvulsant drugs by women with epilepsy and an elevated incidence of birth defects in children born to these women. Reference has been made to primidone in several cases in which it was used *in combination* with other anticonvulsants; but its teratogenicity has not been conclusively demonstrated. The possibility exists that other factors, *e.g.*, genetic factors or the epileptic condition, may contribute to the higher incidence of birth defects. The data also indicate that the great majority of mothers receiving anticonvulsant medication deliver normal infants.

Anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and risk to both mother and the unborn child.

When the nature, frequency, and severity of the seizures do not pose a clear threat to the patient, good medical practice requires that the physician weigh the expected therapeutic benefit of anticonvulsant therapy against possible risk on an individual basis.

Neonatal hemorrhage, with a coagulation defect resembling vitamin K deficiency, has been described in newborns whose mothers were taking primidone and other anticonvulsants. Pregnant women under anticonvulsant therapy should receive prophylactic vitamin K_1 therapy for one month prior to, and during, delivery.

The physician should weigh all of the foregoing considerations when treating and counseling epileptic women of childbearing potential.

PRECAUTIONS: The total daily dosage should not exceed 2 Gm. Since MYSOLINE therapy generally extends over prolonged periods, a complete blood count and a sequential multiple analysis-12 (SMA-12) test should be made every six months.

In nursing mothers: There is evidence that in mothers treated with primidone, the drug appears in the milk in substantial quantities. Since tests for the presence of primidone in biological fluids are too complex to be carried out in the average clinical laboratory, it is suggested that the presence of undue somnolence and drowsiness in nursing newborns of MYSOLINE-treated mothers be taken as an indication that nursing should be discontinued.

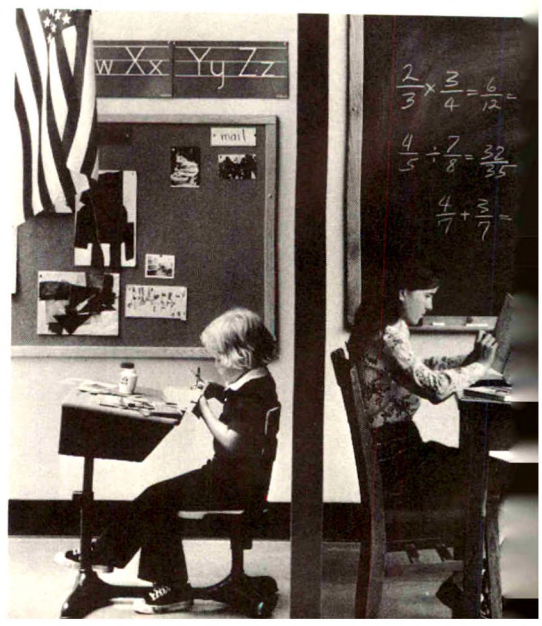
ADVERSE REACTIONS: The most frequently occurring early side effects are ataxia and vertigo. These tend to disappear with continued therapy, or with reduction of initial dosage. Occasionally, the following have been reported: nausea, anorexia, vomiting, fatigue, hyperirritability, emotional disturbances, sexual impotency, diplopia, nystagmus, drowsiness, and morbilliform skin eruptions. Occasionally, persistent or severe side effects may necessitate withdrawal of the drug. Megaloblastic anemia may occur as a rare idiosyncrasy to MYSOLINE and to other anticonvulsants. The anemia responds to folic acid, 15 mg. daily, without necessity of discontinuing medication.

DOSAGE AND ADMINISTRATION: The average adult dose is 0.75 to 1.5 Gm. per day. The initial dose is 250 mg. Increments of 250 mg. are added, usually at weekly intervals, to tolerance, or therapeutic effectiveness, up to daily doses not exceeding 2.0 Gm. A typical dosage schedule for the introduction of MYSOLINE (primidone) is as follows:

Adults and Children Over 8 Years of Age

1st Week 250 mg. daily at bedtime	*2nd Week* 250 mg. b.i.d.
3rd Week 250 mg. t.i.d.	*4th Week* 250 mg. q.i.d.

In children under 8 years of age, maintenance levels are established by a similar schedule, but at one-half the adult dosage. It is best to begin with 125 mg., with gradual weekly increases of 125 mg. a day, to a daily total usually between 500 mg. and 750 mg.



In patients already receiving other anticonvulsants: MYSOLINE should be gradually increased as dosage of the other drug(s) is maintained or gradually decreased. This regimen should be continued until satisfactory dosage level is achieved for combination, or the other medication is completely withdrawn. When therapy with this product alone is the objective, the transition should not be completed in less than two weeks.

MYSOLINE 50 mg. Tablet can be used to practical advantage when small fractional adjustments (upward or downward) may be required, as in the following circumstances:

- for initiation of combination therapy
- during "transfer" therapy
- for added protection in periods of stress or stressful situations that are likely to precipitate seizures (menstruation, allergic episodes, holidays, etc.)

HOW SUPPLIED: MYSOLINE *Tablets*—No. 430—Each tablet contains 250 mg. of primidone (scored), in bottles of 100 and 1,000. Also in unit dose package of 100. No. 431—Each tablet contains 50 mg. of primidone (scored), in bottles of 100 and 500. MYSOLINE *Suspension*—No. 3850—Each 5 cc. (teaspoonful) contains 250 mg. of primidone, in bottles of 8 fluid-ounces.

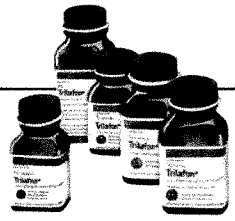
Out of touch

but not beyond reach...

Help restore reality

Trilafon®
brand of
perphenazine, NF
for management of disturbed behavior in schizophrenic and manic states

- low dose, high potency phenothiazine useful for inpatient and outpatient treatment
- helps orient psychiatric patients to their surroundings
- effective with minimal sedation, usually produces little lethargy or drowsiness



Versatile Dosage	
Injection	5 mg/ml, 1 ml ampul
Concentrate	16 mg/5 ml, 120 ml bottle
Tablets	2,4,8,16 mg
REPETABS® Tablets 8 mg brand of repeat-action tablets	

Please see next page for prescribing information.

Trilafon®
brand of
perphenazine, NF

For management of schizophrenic and manic disorders in psychiatric hospitals, mental health clinics, and with outpatient treatment

TABLETS
for maintenance or control of patients in hospital or home

BENEFITS

- generally improve cooperation and communication
- decrease need for custodial care, hasten discharge

CONCENTRATE
for maintenance or control of uncooperative in-hospital patients

- easily mixes with most liquids
- ensures easy, steady, certain administration

INJECTION
for emergency control of uncooperative in-hospital patients

- usually takes effect in 10 minutes
- average duration of effect is 6 hours

TRILAFON® Tablets
brand of perphenazine, NF
REPETABS® Tablets
Concentrate
Injection

CONTRAINDICATIONS TRILAFON is contraindicated in drug-associated central nervous system depression (barbiturates, alcohol, narcotics, analgesics, antihistamines). Perphenazine is contraindicated in the presence of existing blood dyscrasias, bone marrow depression and pre-existing liver damage, and in patients who are hypersensitive to perphenazine.

TRILAFON **Injection** should not be given to patients in coma or severely depressed states.

WARNINGS **Dosage in pregnancy:** Perphenazine should only be given to pregnant patients when, in the judgment of the physician, the potential benefits outweigh the possible risks.

Perphenazine can lower the convulsive threshold in susceptible individuals; it should be used with caution in patients with convulsive disorders. If the patient is being treated with an anticonvulsant agent, increased dosage of that agent may be required when perphenazine is used concomitantly.

Perphenazine should be used with caution in patients with psychic depression.

Perphenazine is not recommended for children under 12 years of age.

Perphenazine may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks, such as driving a car or operating machinery.

PRECAUTIONS As with any potent medication, patients receiving perphenazine should be under medical supervision, particularly if they are receiving high doses. Patients who have had any severe reaction to phenothiazines or to imipramine should be treated cautiously, under close medical supervision.

Although the following adverse reactions have not been reported in patients treated with perphenazine, the possibility that they might occur with TRILAFON should be considered: blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, eosinophilia); liver damage (biliary stasis); narrowing of the visual fields; pigmentation of the retina, cornea, or lens; cerebral edema; polyphagia; photophobia; hyperpyrexia.

If hypotension develops, levarterenol (norepinephrine) can be used, but not epinephrine, because epinephrine's action is blocked and partly reversed by perphenazine. Severe, acute hypotension has occurred with the use of phenothiazines and is of particular concern in patients with mitral insufficiency or pheochromocytoma.

A significant rise in body temperature may indicate an idiosyncratic reaction to perphenazine; treatment with perphenazine should be stopped if this occurs.

The antiemetic effect of perphenazine can obscure signs of toxicity due to overdosage of other drugs, or mask the symptoms of disease (eg, brain tumor or intestinal obstruction).

Contact dermatitis has been reported with a perphenazine solution; therefore, contact of hands or clothing by those handling perphenazine solutions should be avoided.

POTENTIATION Since phenothiazines can potentiate the central-nervous-system-depressant actions of opiates, antihistamines, barbiturates, and alcohol, less than the usual dosage of these agents is required when they are administered concomitantly with TRILAFON. Patients should be cautioned that their response to alcohol may be increased while they are being treated with TRILAFON.

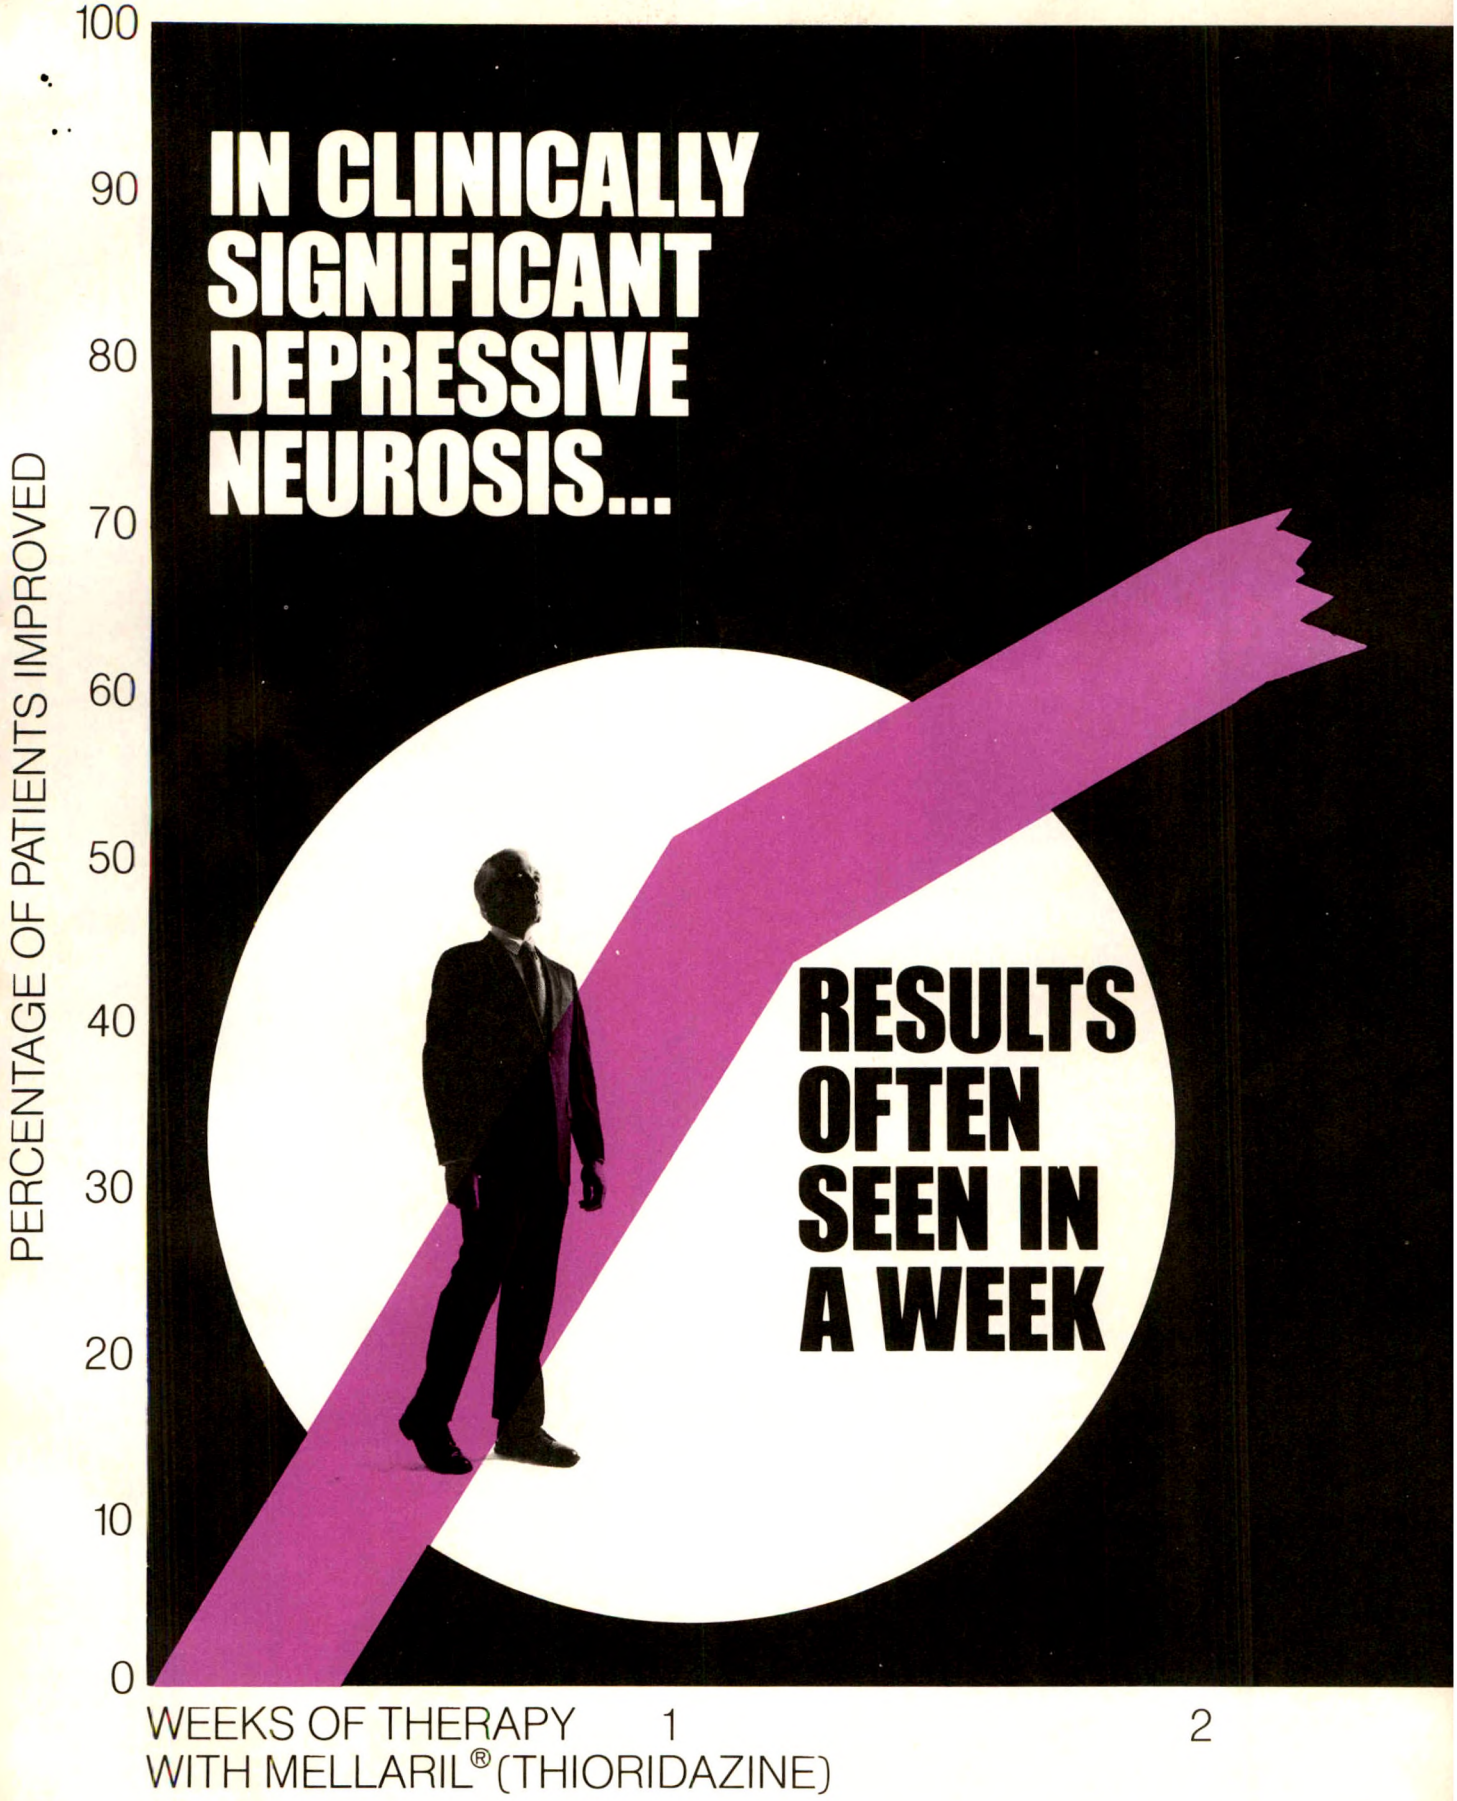
Phenothiazines also potentiate the effects of atropine, heat, and phosphorus insecticides, and should be used with caution in persons exposed to these agents.

ADVERSE REACTIONS *Extrapyramidal reactions:* dystonia including protrusion, discoloration, aching and rounding of the tongue; tonic spasm of the masticatory muscles, tight feeling in the throat, slurred speech, dysphagia, oculogyric crisis, trismus, torticollis, retrocollis, muscle weakness, and aching and numbness of the limbs; akathisia; motor restlessness; dyskinesia, parkinsonism; hyperreflexia; and ataxia. The incidence and severity of these reactions usually increase with increased dosage, but have occurred in some patients receiving low dosage. Reduction in dosage or treatment with an antispasmodic agent will usually control extrapyramidal reactions. In some instances, however, these reactions may persist after discontinuation of treatment with perphenazine.

Persistent tardive dyskinesia: As with all antipsychotic agents, tardive dyskinesia may appear in some patients on long-term therapy or may appear after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (eg, protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities. There is no known effective treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been reported that fine, vermicular movements of the tongue may be an early sign of the syndrome, and if the medication is stopped at that time the syndrome may not develop.

Allergic reactions: erythema, pruritus, urticaria, eczema, anaphylactoid reactions, and local and generalized edema. In extremely rare instances, individual idiosyncrasy or hypersensitivity to phenothiazines has resulted in cerebral edema, circulatory collapse, and death. Photosensitization, asthma, and exfoliative dermatitis have also occurred in patients treated with phenothiazines.

Autonomic reactions: blurred vision, dry mouth or salivation, nasal congestion, nausea, vomiting, hypertension, tachycardia, hypotension, anorexia, urinary frequency or incontinence, and constipation. Significant autonomic effects have been infrequent in patients receiving less than 24 mg. perphenazine daily.



Other reactions: endocrine disturbances (lactation, gynecomastia, galactorrhea, disturbances in the menstrual cycle), headaches, mild insomnia, altered cerebrospinal fluid proteins, ECG abnormalities, reactivation of psychosis, paradoxical excitement, paranoid-like reactions, catatonia, and systemic lupus erythematosus-like syndrome. Hypnotic effects appear to be minimal, particularly in patients who are permitted to remain active. The following adverse reactions, though rare, have also been reported to be associated with perphenazine treatment: agranulocytosis; jaundice; hyperpigmentation of the skin; grand mal convulsions; failure of ejaculation; hyperglycemia.

Side effects with intramuscular TRILAFON **Injection** have been infrequent and transient. Dizziness or significant hypotension after treatment with TRILAFON (perphenazine) **Injection** is a rare occurrence.

SWW-5320

SANDOZ SAN 6-598

For details of study and brief summary, please see following page.

Mellaril (thioridazine) can help you cope with the problem of depressive neurosis because it often produces measurable improvement by the end of the first week of therapy. In 14 double-blind studies, 339 patients with depressive neurosis received Mellaril for four weeks. In these studies, 174 patients (51.3%) improved measurably by the end of the first week, and a total of 293 (86.4%) improved during the four weeks of therapy. Furthermore, 55% of the overall improvement was observed by the end of the first week.

Mellaril usually does not cause euphoria or undue sedation and is not habituating. Patients, therefore, generally remain alert and better able to respond to therapy. (The physician should, however, caution patients against participating in activities which require complete mental alertness, e.g., driving.)

MELLARIL®
(thioridazine)

TABLETS: 10 mg, 15 mg, 25 mg, and 50 mg thioridazine HCl, U.S.P.

for the short-term treatment of moderate to marked depression with variable degrees of anxiety in patients with depressive neurosis

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg. should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling.

The following reactions have occurred with phenothiazines and should be considered: *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

Dosage: Dosage must be individualized according to the degree of mental and emotional disturbance, and the smallest effective dosage should be determined for each patient. In adults with depressive neurosis the usual starting dosage is 25 mg t.i.d. and the dosage ranges from 10 mg b.i.d. to q.i.d. in milder cases to 50 mg t.i.d. or q.i.d. for more severely disturbed patients; the total daily dose ranges from 20 mg to a maximum of 200 mg.

THE AMERICAN JOURNAL OF PSYCHIATRY

Overview: Research on the Psychology of Women. II. Women in Families, Work, and Psychotherapy

BY ANNE M. SEIDEN, M.D.

In the first part of this overview the author reviewed research on gender differences in behavior and women's sexual and reproductive lives, and discussed the social and intellectual context of the recent knowledge explosion in women's studies. In this second part she reviews recent research on selected aspects of the social psychology of women's lives. Highlighted themes include women in relationship to family structure and child rearing, work and achievement motivation, and implications for the psychiatric treatment of women that can be drawn from the psychotherapy research literature. She briefly assesses the possible impact of research in these areas on psychiatric theory and practice.

ALL HUMAN CULTURES have some form of family or family-like grouping. In addition to "expressive" functions in living and loving, families serve multiple "instrumental" (1) purposes: to pool economic resources, support and stabilize adult personalities, and provide support in illness and disaster, as well as to share the tasks of child rearing and childhood socialization. Family and kinship networks may be built around a matrilineal or matrilocal family, patrilineal or patrilocal family, or other groupings of real or fictive kinship networks.

This paper was written at the invitation of the Editor.

Dr. Seiden is Director of Research, Institute for Juvenile Research, Illinois Department of Mental Health and Developmental Disabilities, 1140 South Paulina St., Chicago, Ill. 60612. She is also Assistant Professor, Department of Psychiatry, Abraham Lincoln School of Medicine and the School of Public Health, University of Illinois, Chicago, Ill.

The author wishes to thank Shiaomay Young, M.A., for bibliographical research, Marlyn Grossman, Ph.D., for editorial assistance, Estelle Marvel and Joann Brown for manuscript preparation, and a number of colleagues who provided valuable stimulation and suggestions at various stages in the preparation of this paper.

FAMILY STRUCTURE AND CHILD REARING

Recent Western culture, and particularly American culture, is relatively unique in having as the norm a small nuclear family, with few enforceable obligations resting on other kin. This nuclear family is both highly mobile (the average duration of a mortgage in the United States is said to be 4 years) and often unstable (in 1975 the divorce rate of 4.8 per 1,000 population approached almost one-half of the marriage rate of 10.0 per 1,000 [2]). The contemporary isolation of many nuclear families from the tribe or extended family, with disruption of the female-female bonding system characteristic of many primates and traditionally dwelling humans, is a relatively new characteristic of mobile industrial societies (3). Particularly new is the combination of crowding-in-isolation (that is, a nuclear family crowded into a few small rooms, coexisting with relative social isolation of a housebound mother from extended family and other familiar adults). For primary child care, contemporary American society is distinctly unusual in relying far more heavily than most cultures on mothers alone, with variable but relatively little participation by older children, husbands, or other kin (4).

The "trapped young mother" syndrome has received extensive attention in the public media, and a number of studies have found that children add stress to parents' individual or marital lives in this culture. Studies of the 1960s, reviewed by Hicks and Platt (5), found children to detract from marital satisfaction. A major recent Quality of American Life Survey (6) found a sharp difference in reported satisfaction with life as a whole between young, married, childless women (89% satisfied) and married women with young children (65% satisfied). Indicators of psychological stress were greatest for both men and women during the early parental life stage.

The apparent effects of some of the previously discussed variables on the psychology of women have

been to increase the importance of the heterosexual bond without necessarily increasing its stability, while decreasing the importance of other social bonds, such as those to kin, friends, and neighbors. The issue could be phrased as follows: one of our great national problems appears to be a maldistribution of child-care experience; some full-time housewives suffer from excessive contact with children and relative deprivation of contact with adults, while other members of our society may be virtually isolated from any meaningful contact with small children.

Day-care centers that are well run and employ adults who have chosen child care as their work have found that about 6 hours of direct child care per day is an optimal maximum (7). Full-time housewives may significantly exceed this, but by contrast, one study (8) found that a sample of middle-class husbands spent less than *one minute* per day in direct contact with their infants. This is a keenly felt deprivation for some men (9). Similarly, children in small families may grow up without any real experience in caring for younger siblings, and women whose children have left the home may mourn the total loss of child contact. Maccoby and Jacklin (10) have discussed evidence of the advantages of caring for younger children in the socialization of older children, and Goodall (11) has pointed out that some sharing of child care is common among chimpanzees, as it is in less industrialized human cultures (4).

There is a widespread belief that the structure of the American nuclear family has deteriorated. It has certainly changed. Our divorce rate is the world's highest. Although 80% of all divorced persons eventually remarry, children may spend prolonged periods of time with an overburdened single parent. In 1970 over one-fourth of American children under age 18 (and over half of our black children) were not currently living with both natural parents (12). It is estimated that by the time they reach 18, 35% to 45% of all American children will have spent an average of 5 years in a single-parent home (13). This is a sizable percentage, and it may reflect the fact that the divorced group who in a sense may need the support of a marriage most, i.e., parents of young children, may have the least opportunity to meet and bond with another spouse.

There are other striking changes in American family structure. In 1890 the average household consisted of 5 people, but in 1974 it was less than 3 due to fewer children and fewer other relatives in the home (14). Historical studies have indicated that the communally dwelling extended family was more characteristic of land-owning farm families than of urban ones (15), a condition that was in itself characteristic of a higher proportion of our population in 1890.

All of these problems are probably considerably greater in industrial society than previously because of the greater number of hazards that require close supervision of children and prevent their sharing in adult work and because of the marked increase in the length of the period of childhood dependency. Age 14, formerly the average year for entry into the adult work force, is today considered *early* adolescence—a period close to childhood during which the adolescent is often felt to require close parental supervision. The fact that we have not yet fully integrated the changed conditions over the past 100 years may represent a culture lag that is currently being addressed.

Effects on the Mental Health of Women

What effects do these unusual features of recent American family life and child-rearing conditions have on the mental health of women—and children? Much of the available data lies more in the realm of social commentary than research.

Moynihan—himself a successful product of a home broken by death—attracted considerable attention by attributing black poverty and other social ills to the prevalence of single-parent homes (15). It is true that studies of child abuse (16) and of the psychological readiness of 6-year-olds for school (17) indicate the relative vulnerability of a single adult in caring for children, particularly under conditions of poverty. (However, the critical protective factor appears to be the presence of more than one adult, not the question of whether that other adult is a father, stepfather, grandmother, or even the mother's female friend.)

Mental health statistics have shown that married women are more likely than the unmarried to seek psychiatric help (18), to attempt suicide, and, even if nonpatients, to report somatic symptoms indicative of psychological distress (19). In apparent contrast, the Quality of American Life Survey (6) reported that women as a group *exceed* men in self-reported overall life satisfaction under the following circumstances: married, aged 18–29, no children (17 percentage points greater satisfaction); never married, over 29 (12 points); never married, aged 18–29 (11 points); widowed (6 points); or married with children (3–1 points, declining as the children are younger). The greater life satisfaction of women over men thus appears to be very small for married women with children, much smaller than in other life circumstances. The possibility that even this small difference reflects defensive self-reporting is suggested by the higher incidence of suicide attempts and somatic symptoms in women compared with men in the same age range. In summary, single and widowed women report themselves as being satisfied more often than do single and widowed men; this difference increases during early marriage if there are no children but almost disappears if there are children. However, divorced women report themselves as significantly less satisfied than divorced men. Most have severe economic and emotional burdens in child rearing. Only 14% are awarded alimony, and only 44% are awarded child support. Less than one-half of these, i.e., 21% of all divorced mothers, collect child support regularly, and even then the payments are generally grossly insufficient (2).

Thus there is a striking contrast between the traditional belief that women require marriage and children

for psychological fulfillment more than men do and the evidence that marriage, and especially the child-raising period, is associated for women with less happiness, more stress, and more overt mental illness. How does one account for this contrast?

One possibility, of course, is that women have simply been "sold a bill of goods"—been raised without accurate information about the toll that marriage and child rearing may have on their lives. Another possibility is that marriage and parenthood, like other desired goals, may be *both* a genuinely desired challenge and a source of stress and therefore increased risk of impaired physical and mental health. It is certainly not unknown for people to seek other pleasures, such as smoking, skiing, or high-pressure jobs, despite their known hazards to health or happiness. The research literature attempting to quantify stress in relationship to illness has clearly suggested that positive life events may be as stressful as negative ones (20).

It is highly likely that some of the toll exerted by child rearing and perhaps marriage as well arises from intrinsic stress and lack of accurate anticipatory information, as well as from lack of economic support. This suggests that it is important for both clinicians and the population at large to have a realistic appraisal of the occupational hazards of child rearing and the need for adequate support and backup. We are not in a good position to understand and mitigate these costs if we simply deny them.

Changes in Child-Rearing Practices

A variety of approaches is currently being used to mitigate the psychological costs of child rearing, while preserving the benefits. Currently, women themselves are increasingly seeking extrafamilial employment during the child-rearing years (21) and planning on having smaller families (12). The generally low salaries received by employed women suggests that the motives for employment are not entirely economic (21).

Suggestions have been advanced for the modification of men's career patterns (9), provision of professional or neighborhood day-care homes (22), employment of "foster grandparents," and the like (23). Even the realistic appraisal of stress and symptoms as a time-limited occupational hazard, rather than necessarily evidence of personal pathology, might be expected to be beneficial. Few of these suggestions have been implemented on a large scale, and fewer still have been carefully evaluated in terms of their impact on the satisfaction and health of women, men, and children. This appears to be an important area for social-psychological and clinical research in the future.

PSYCHOLOGY OF WOMEN AT WORK AND IN THE COMMUNITY

Some of the material pertinent to this section has already been examined in the discussion of child rearing. This is appropriate, since housekeeping and child rearing are work, whether they are counted as employment or not. In addition, the burdens and satisfactions of housework and child care continue to fall more heavily on women than men, regardless of the women's employment status (24). Sometimes this is by the women's choice, sometimes it is a matter of guilt, and sometimes it reflects an unrealistic commitment to the "superwoman" role. Childhood socialization may play an important role in that the woman who has already learned how to cook, clean, and manage a household efficiently may despair of teaching those skills at a later age to a husband who has not learned them. Even women who are employed have been observed to teach household skills to and require household duties from daughters more than sons (25), a situation that is likely to perpetuate the imbalance. Perhaps all of us would enjoy the idea of having a personal servant, and to some extent, enjoying this role vicariously by performing it for others may be easier than giving it up. It is also true that in work situations there is still a pronounced trend toward failure to recognize women's real competence (26), and the maintenance of domestic competence greater than her husband's may remain a source of compensatory self-esteem for the woman employed outside the home as well as in it.

Bardwick (27) summarized evidence showing that the present cohort of middle-aged women begin to evidence increased dissatisfaction with a housewife-only role after about 10 or 15 years. Whether this length of time will continue to be salient is a matter of speculation, but current data (28) suggest a sharp increase in the number of college women with plans for little if any interruption of their careers.

At present, most adult women are employed outside the home; they constitute 40% of the paid labor force (29, p. 33). Statistically, they hold lower-status, lower-paying jobs than men do, a gap that is widening rather than narrowing (29, p. 47). This condition may pose psychological if not economic problems for the relatively affluent married woman whose husband provides support and family status. However, a substantial number of women provide total or major support for themselves and their families, if any; and another substantial portion are keenly aware of the need to have their daily activities receive social validation in terms of money and/or respect. Guilt about or pragmatic conflict between the demand of occupational roles and maternal roles sometimes poses problems for women (30). This is in large part a function of the woman's income and job status: absenteeism, including that for child-care reasons, is slightly higher among female than male employees (5.6 versus 5.5 days per year). "Quit rates" for women are higher than for men (24 per 1,000 versus 18 per 1,000) and notably so among the higher proportion of women in less skilled jobs, who lack control over their working hours and receive pay at about the same level as available surrogates (31). Of course, fathers rearing children alone have many of the same problems, and their number is increasing with the acceptance of single-parent adop-

tions and the decrease in the convention that the mother is automatically to be favored in obtaining custody after divorce.

The increasing number of women who say they are working for fulfillment rather than or in addition to economic necessity deserves serious consideration. Pay may not do much more than cover increased expenses due to employment. There are those who wonder about this trend, noting the apparently mundane character of many jobs that are taken for "fulfillment." Ultimately, this will require reexamination of our assumption that only well-paid, high-status, or influential jobs provide fulfillment. It is probably a remnant of the American upward mobility-success tradition. The need for companionship in one's daily activities is fairly widespread, as is the need for producing a tangible product, which household maintenance does not.

There is now an extensive body of work on motivation for occupational achievement in women. Horner's early studies (e.g., reference 32) suggested that some kinds of achievement that were relatively unambivalently valued by male college students were perceived as dangerous or conflictual for college women. She postulated a fear of success among bright women. A number of replications and extensions in this area have begun to tease out some of the relevant variables. For example, success motivation for competitive tasks in men tends to disappear in the absence of an audience, while the opposite appears to be true for women (33). These and other studies suggest that achieving women have learned to fear that society might punish them for that achievement, particularly if it is perceived as deviant, while achieving men have learned to expect societal reward to maintain their behavior.

The large body of literature on conditions of work for employed women and the effects of their employment and employment conditions on children has received four major fairly recent reviews (21, 34–36). The trend of this research appears to indicate that children do best overall when mothers who prefer to be housewives can be housewives and when mothers who prefer employment can have it. While earlier work had looked for and found adverse effects of employment among mothers (such as inadequate supervision, especially among poverty groups), more recent work has looked for and found both positive and adverse effects, both of which occur in interaction with other variables. For example, in one study of working-class depressed women and normal neighbor controls (37), the percentage of employment was about the same among both groups, but the depressed women were more likely to dislike and function poorly at their jobs and to have impaired relationships with their children, regardless of whether the job was that of a housewife or a paid employee. Interestingly, in another study (38), employed women recovered more quickly from depression than housewives, even when they were employed because of economic necessity. The household milieu may be understimulating for a depressed woman, even if she prefers it when not depressed.

Women's Friendships and Love Between Women

There is now a growing body of literature regarding female-to-female social networks at present and historically (39). It is interesting that much of this discussion is also relatively new. Normative social-structural models have been based on the heterosexual pair or the male-male bond as the primary units of the social structure (40). In these models female-female bonds are regarded as of secondary importance, supportive to the social structure or a way of filling in time in the absence of the "more important" heterosexual or mother-child bonds. Yet there is abundant evidence that women's friendships have always been an important part of the social fabric, relatively neglected only in early 20th-century social theory (41).

As Smith-Rosenberg (41) observed, extremely close, warm, devoted relationships between women were common in previous years and were expressed openly in affectionate correspondence that has apparently been a source of embarrassment to some modern historians. Major areas of help that women gave to each other, and continue to give, include emotional support in times of crisis or loneliness and practical help with such events of the female life cycle as birth, gynecological problems, and illness and care of the sick. There is a fairly widespread tendency to disparage the kaffeeklatsch conversation of women, but research on widowhood has disclosed that a greater number of men have intimate conversations only with their wives, while women are more likely to have a female confidante as well. The fact that the mental health and happiness of single and widowed women is generally better than that of single and widowed men has been attributed in part to the supports available from female friendships (42).

Some women who previously felt competitive or anxious with other women have cited the women's movement as providing them with significant female friendships for the first time. However, a pilot study of friendships among women active in the movement did not confirm this as a representative development (39). Most of these women had had important friendships with women all their lives; what the movement had provided in most cases was a new legitimation of the value of these friendships.

The distinction between close female friendships and lesbian relationships appears to have been confusing for many professional and popular writers. There has been a significant scotoma in both law and social science, which may have worked to the advantage of lesbians: laws against homosexual behavior have almost never been enforced against women, although there have been some recent problems concerning child custody. Smith-Rosenberg (43) noted that Victorian medical texts, fearing the imagined dangers of masturbation, noted that "some of these girls [in boarding schools] teach each other to masturbate,

and some of these women do not want to marry" without apparent awareness that "teaching each other to masturbate" referred to lesbian sexual relationships.

In fact, lesbian women make the same distinction between friends and lovers that heterosexuals do, and heterosexual women do not appear to be as confused or anxious about the distinction between close friendship and sexual intimacy as men do. "Homosexual panic" as a clinical entity appears to be far more common among men than women, although Deutsch (44) theorized that it might be a problem for widows.

Until recently, there appears to have been a relative paucity of research literature on lesbianism and an even greater neglect of what research was available. Thus Sherman (45), in a relatively comprehensive and recent text on research on the psychology of women, had no section on the topic. A bibliography from the American Psychological Association on the psychology of women (46) contains only four references to lesbianism, and only one of them is a research paper. A bibliography from the National Institute of Mental Health (47) lists only six research papers. These studies, for the most part directed at comparing the prevalence of symptoms in heterosexual and homosexual male and female samples, generally found small differences or none. (Several studies showed a slightly higher frequency of depression, drug use, or suicide attempts among homosexual populations, but a majority of the homosexuals functioned as well as the controls on the dimensions studied.)

The literature reviews that do exist (48, 49) do not include references to studies of lesbian women as mothers, which is a serious omission in view of the fact that expert testimony is often sought in child custody disputes. Recent research is filling in this gap (e.g., reference 50).

The available literature indicates that lesbians tend to have or seek lasting relationships more frequently than male homosexuals do (e.g., reference 51). One recent study comparing unmarried young lesbian women to their heterosexual counterparts (52) found that both groups had about the same percentage of transient, deepening, and cohabiting relationships expected to be permanent and about the same percentage of depression and other psychiatric symptoms. Both groups, of course, are under some similar social pressures, e.g., to marry and/or to conceal the status of their sexual relationships. The fact that these pressures are generally conceded to be considerably greater for lesbians might have predicted a greater incidence of symptoms, but this was not found.

Lesbian relationships in previously heterosexual women are beginning to receive some research attention. In some cases the women themselves regard their previous heterosexual experience as an attempt to deny a lesbian orientation that they trace to earlier years. However, there is also a distinction between "political" and "personal" lesbianism. That is, there are some women who have felt that participation in the women's movement either ideologically contradicted, or personally made difficult, relationships with men (39, 53). Confining love relationships as well as friendship relationships to women then became a political statement or a practical necessity or both.

IMPACT OF RECENT RESEARCH ON THE CLINICAL TREATMENT OF WOMEN

Depression and Schizophrenia

The literature on depression is of obvious pertinence, since a greater proportion of patients diagnosed as having overt clinical depression are women, with reported proportions varying from 2:1 to 3:1 (54, 55). Genetic research has suggested that endogenous affective disorder may be transmitted as an X-linked dominant gene, thus giving women twice the vulnerability of men (56). At the same time, ego-psychology, sociological, behavioral, and animal models converge on noting the similarity between the "learned-helplessness" model of vulnerability to depression and stereotypical female sex role expectations (57). While continued controversy in this area is likely to be with us for some time, integrative models are appearing, and the attention given to the controversy itself is likely to heighten clinical attention to diagnostic criteria. At the very least, "learned helplessness" would appear to pose special hazards to persons biologically vulnerable to depression, while exclusive attention to either social causes or their psychodynamic reflections would run the risk of ignoring biologically treatable conditions.

While schizophrenia is currently a condition that is more likely to be diagnosed in men than women, the whole subject of the true prevalence of schizophrenia is at present considerably clouded. It appears likely that in American psychiatry there has been a trend to 1) overdiagnose schizophrenia when bipolar affective disorder would now appear to be the more accurate diagnosis (58) (thus perhaps overrepresenting women among the listed hospital schizophrenic populations), and 2) diagnose schizophrenia more often in men than women, in that the marginally functioning but quiet and nonviolent schizophrenic, more often female, may never be hospitalized and thus not receive a diagnosis. (In other words, schizophrenia together with male aggressiveness may be perceived as more dangerous and therefore may be more likely to result in hospitalization.) Thus the true prevalence of the disorder in men and women is unclear and is likely to remain so for some time.

In Chesler's intriguing social-psychological model (59), depression is seen as a disorder consisting of exaggerated female sex role behavior, while schizophrenia in both sexes is seen as a disorder based on radical rejection of assigned sex roles. While the clinical observation appears accurate—schizophrenic patients of both sexes *are* frequently conflicted about gender-prescribed behaviors and even basic gender identity—I lean toward regarding this as a secondary

symptom rather than a primary one. It seems more likely that the elaboration of sex differences and roles that our society, like others, has expected at adolescence (a time at which many schizophrenics begin to experience especially severe difficulties) is sufficiently complex and unrealistic enough to make it harder for a person with a basic schizophrenic thought disorder to navigate the course. If this is true, relaxation of sex role rigidities would not be expected to reduce the true prevalence of schizophrenia, but it might have the important effect of decreasing the magnitude of the adaptive task for schizophrenics (and others).

Psychotherapy Research

The field of psychotherapy research is enormous, complex, and fascinating. Probably the most solid finding in the entire body of work is one that is frequently ignored because it is, of course, threatening to us as clinicians: psychotherapy has the potential for accelerating deterioration as well as producing beneficial effects under certain conditions that are not entirely understood (60, pp. 246–252; 61). While this is what one would expect of any powerful therapeutic agent, we have been hampered in applying appropriate cautions by a relative lack of solid data about specific therapeutic conditions that should be cause for concern. Current feminist work may be helpful in bringing the question of adverse effects back into the central focus that it deserves. Specific criticism by feminists has highlighted the following areas (also noted by others):

1. Sexual abuse of the therapeutic relationship is more common, and at least sometimes more devastating, than has previously been recognized (61). Problems in this area may be further compounded by the therapist's use of overt or covert threats of various sorts to prevent disclosure (62, 63).

2. The perhaps more subtle but related danger is that the therapeutic relationship in a dyad may replicate rather than remedy the "one-down" position in which women frequently find themselves in life and marriage, thus encouraging the fantasy that an idealized relationship with a more powerful other is a better solution to life problems than taking autonomous action (59).

3. Therapeutic theories have more often supported rather than questioned stereotypical assumptions about sex roles, with different standards of mental health for women and men (64), including the assumption that dependency, masochism, and passivity are normal for women and the tendency to treat assertiveness and aggression differently for women than for men.

4. Women specifically, especially when treated as collaterals to their children, may be harmed by a "blame-the-mother" tradition in clinical psychopathology (vide the considerably greater and earlier literature on allegedly schizophrenogenic mothers than fathers, despite the lack of clear evidence that either is specifically responsible for the more serious disorders of their children).

5. There has been a lack of realistic appraisals of the occupational hazards of the housewife role.

Special Issues Related to the Gender of the Therapist

While therapist gender is often considered in making an assignment of clinic patients, there are relatively few solid data on differential outcomes by diagnosis and other patient characteristics. Luborsky and associates (65) found that in dynamic psychotherapy, favorable outcomes were more often obtained when the therapist and patient resembled each other in terms of *all* measured demographic variables (including gender, age, marital status, religion, and social class origin). Orlinsky and Howard (66, 67), reanalyzing data from the 1960s, were able to make more precise recommendations for female patients. They found that having a female therapist was more likely to predict a successful outcome for women patients as a group but that most of the variance was accounted for by women who 1) were relatively young and unattached (i.e., not married or mothers), and 2) had a diagnosis of depression. In this age-diagnostic group they found that with male therapists, more time was spent talking about the therapeutic relationship itself, including erotic transference, but that female therapists were more likely to be perceived as supportive and helpful and were more often associated with overall patient satisfaction. For women in other life-status and diagnostic groups, these differences between male and female therapists were less pronounced.

It has been argued, quite possibly with some merit, that the gender of the therapist is less important in psychoanalysis than in therapies of lesser intensity and extensiveness. This argument states that there is time and scope in an analysis for the development and resolution of both maternal and paternal transferences, regardless of the therapists' and patients' actual genders. Even assuming its validity, the argument would be more persuasive to analysts who hold that the formation and resolution of transference neurosis alone is the effective ingredient in analysis; it would be less persuasive to those who hold that corrective emotional experiences, or provision of role models, are also important ingredients. Actual data on differential outcome are relatively rare.

Regardless of the ultimate preference that different kinds of female patients have for a therapist of the one or the other gender, there are a few issues in therapist training that are likely to have a special impact on the work of female and male therapists with female patients.

Female therapists are much less likely to have had as many supervisors of their own sex as role models during training; some may have had none (68). In this regard they may be more likely to have experienced conflict between their therapist identity and their own gender identity. If this issue is worked through it is likely to have been perceived as a source of professional growth (69), but if it is denied there may be special problems in identifying with less privileged wom-

en. The conscious or unconscious position that "there is no problem; if I could succeed so can you" can be a bar to empathy, as can a countertransference position of pleasure at seeing women like those who in high school belonged to a popular social set now developing problems that the therapist—perhaps a "grind" in high school—now escapes (70). In addition, perhaps because of a relative lack of female supervisors, and perhaps because of a general cultural denial of women's homosexual feelings, homoerotic transference issues may have been less carefully dealt with in the supervision of female therapists with female patients.

Male therapists are likely to share in the dearth of female supervisors and therefore have more learning experience in the discussion of women's difficulties from a male perspective than from a female perspective, where these perspectives differ. Androcentric bias in the male therapist ("male chauvinism") is probably less likely to have been corrected in professional training than gynecocentric bias in female therapists, who generally receive extensive exposure to male psychiatric points of view. Erotic transference cuts both ways in the male therapists' treatment of female patients: it may provide for a more rapid mobilization of interest in the therapeutic relationship and may provide either gratification or anxiety for the male therapist, but he is likely to receive supervisory help in that male supervisors have generally shared this experience. Since the female patient and male therapist (like most persons) are more likely to have had a closer early relationship with their own mothers than their fathers, collaboration in a mutual recognition of anger at the mother and their problems with her may speed the reevocation of oedipal feelings but slow the resolution of them.

None of these problems is by any means insuperable, but more explicit recognition of them in training and the provision of supervisors of both sexes for work with patients of both sexes is likely to be helpful.

For all therapists, it is likely that changing roles and expectations of women and men are likely to bring new issues in this area into focus in treatment over the next few years. Further, therapists of both genders may well find that gender-specific transference and countertransference issues that they learned to recognize and handle during training may change over the life cycle as the therapist's own age, marital status or satisfaction, and life circumstances change. Continuing education and occasional consultation may be very helpful in keeping up with both the changing times and the therapist's own changing experience of these issues.

Effects of the Women's Movement on Clinical Treatment

Data on the effects of participation in feminist activities on the mental health or psychological organization of women are thus far sparse and largely anecdotal. Some individual women speak with great enthusiasm of their own gains from participation in the movement, indicating at the very least a charismatic effect of the sort that Vaillant (71) recommended as an alternative treatment modality. Bernardez-Bonesatti (72) showed that there were differences between feminist and nonfeminist applicants for outpatient psychotherapy, with feminists showing less passivity and greater self-esteem.

Feminist therapy, even when provided by well-qualified professionals, has attracted some degree of suspicion regarding both its clientele and the therapy itself (73). While suspicion within the women's movement centers on the motives for a therapist's willingness to take an elite position and charge a substantial fee, suspicion from the professional side is more diffuse. At a recent annual meeting of the American Psychiatric Association, in a session on feminist therapy, two psychiatrists in widely different parts of the country described their male colleagues' apparent anxiety at the idea of all-women therapy groups (74, 75), despite the fact that same-sex therapy groups have been widely used for other groups such as prisoners, the clergy, and adolescents. Economic issues may be one explanation; in major metropolitan areas female psychiatrists currently report that they have insufficient time to accept all their referrals at a time when some male psychiatrists are having difficulty filling their schedules. Feminist therapists have reported their experience in successfully treating women who felt that they had prior treatment failures with nonfeminist therapists, and the reverse also occurs (76).

At present, feminist therapy has some of the characteristics of a "school" of psychotherapy, although, of course, many members are also adherents of other therapeutic schools or of informed eclecticism. Feminist therapy has its own rosters of therapists, body of research and clinical literature, and special sessions at major meetings of mental health professionals.

Major trends in feminist therapy appear to include a grounding in current research about women, a relative priority given to environmental interpretations rather than intrapsychic ones, and a trend toward greater egalitarianism between therapist and patient. Other characteristic trends include a careful avoidance of using the therapeutic situation to replicate the one-down position that women often take in marriage or work, a hearty laugh at the idea that a healthy woman is characterized by passivity, and an attempt to provide a good role model in the form of a competent woman. None of these characteristics taken individually distinguishes feminist therapy from all other schools, but the constellation apparently is either unique enough, or perceived as unique enough, to have created a demand.

There are, of course, risks. For example, the previously reviewed literature on the "fear of achievement" suggests a prevalence of internalized conflict about achievement among many able women with achievement goals. In therapy a total neglect of internal conflict might lead to ineffective therapy in these and other areas. There is a further risk in that feminist

patients are no more immune to organically determined disorders than are other people, and thus far a majority of feminist therapists are not psychiatrists. For example, a woman with a genuine bipolar affective disorder, who needs pharmacological as well as psychotherapeutic help, may have difficulty in finding a therapist who is both a pharmacologically competent psychiatrist and a feminist, or a psychiatrist who is willing to collaborate with a feminist therapist.

DISCUSSION

It should be clear from this overview that we now have available a large body of recent and important research data on women that must be sifted, evaluated, and fed into the development of appropriate theory about women. This paper is intended to be a step in that direction, but one that is necessarily preliminary at this time. Since the body of research referred to has largely been produced within the last decade, much of it during the early 1970s, it appears unlikely that we will have a body of studies that have been replicated, critically reviewed, and assimilated into the field before the next decade. In the meantime there will be a considerable need for psychiatric researchers (and, of course, researchers in related fields) who possess a diverse repertoire of research skills and familiarity with the literature in this field. Urgently needed will be women's studies scholars who cross disciplinary lines, e.g., having *both* clinical experience and knowledge of historical, anthropological, sociological, or psychometric methodologies.

Importance of Recent Research to Psychiatry

There appears to be considerable potential for an exciting enrichment of general psychiatric theory, research, and practice. For example, in a fairly recent review of psychiatric research during the period 1963–1972, Brodie and Sabshin (77) reached the following conclusions, among others:

> One of the striking findings of this survey involves the paucity of papers on the social causes of psychiatric illness. Social psychiatric concepts had produced important formulations about etiology during the 1950s . . . [78, 79], and by the beginning of the 1960s it appeared that we were on the verge of developing new constructs to account for social factors in psychopathology. Quite clearly, these new constructs have not emerged between 1963 and 1972 and this void may represent a significant commentary on the past decade. (p. 1316)

There are a number of reasons for believing that research in the area reviewed here may contribute in the future to the breakthrough that Brodie and Sabshin had anticipated but did not find in the 1960s or the early 1970s.

1. The implications of sex-role typecasting for psychopathology or symptom expression are just beginning to be plumbed. As Dohrenwend and Dohrenwend noted in a comprehensive review of the influence of social and cultural factors on psychopathology (19), it has been difficult to compare the major psychiatric epidemiological studies. Major questions of theory, which in some instances could turn on questions of fact, have been left unresolved because of methodological problems. These problems include overlooking sex-role differences. For example, women are consistently shown as more likely to be diagnosed as neurotic, and men as sociopathic. But whether sociopathy is considered to be "mental illness" varies so greatly from study to study as to make results noncomparable. Widely used symptom scales, such as the 22-item screening instrument from the Midtown Manhattan study (80), "are more representative of female than male modes of expressing distress" (19). Clearly, before the complex literature on social causes can be sufficiently clarified to yield grounded theory, it will be essential to give the kind of careful attention to sex differences that has been characteristic of the current work. This will involve carefully looking for sex differences and attempting to pin down their sources rather than using stereotyped explanations, as well as giving careful scrutiny to alleged sex differences to see whether the data really support their existence.

2. The current research includes much work on the distinctive events of the female life cycle, such as the biopsychological and sociopsychological aspects of menarche, sexual relationships, childbirth, lactation, early mother-infant bonding, and menopause. This is studied in relationship to other events of the female life cycle that are not uniquely female, such as education, employment, child care, adaptation to illness, bereavement, and aging. Although many of these topics have been studied in previous research, we have had surprisingly little integrative work uniting them. The newer work will be important both in understanding the etiology and pathogenesis of psychological distress in women and in understanding women's participation in social networks that alleviate or exacerbate psychological distress in others.

3. For the first time we have a large number of well-trained investigators who are doing research on women and who are women themselves and have experienced a number of the life events under study. The issue is similar to that regarding studies of other minority groups; while no one would be likely to make a convincing argument that *all* of the research about a particular minority group should be done by members of that group, there are compelling reasons why *much* of it should be (81). Researchers from a privileged group outside the group being studied are at risk of having shallow conceptualizations, lack of empathic understanding of the salient variables, and perhaps a different axe to grind. Further, there has been a strong criticism that research done from the "outside" is not as likely to be conceived or later used in a way that benefits the people "inside" the group in question. A persistent concern in psychiatric research related to social problems has been the considerable gap between

research and application. Sometimes the gap may occur because the investigators themselves are not particularly interested in implementation and sometimes because the research is too poorly conceived to merit application. The infusion of numbers of investigators who belong to the group whose ox is being gored is probably the best remedy to this situation, and it can be expected to result in better research and quicker dissemination and application of findings.

4. It is even possible that the current increase in the number of women entering medicine and psychiatry, and the rapid expansion of women's studies as a related research field, may yet contribute to the hoped-for transformation of psychiatry into a more research-oriented field (82, 83). This appears to have already occurred within the field of psychology, where the great discrepancies between what women have experienced for themselves and what psychological theories say about women have acted as a powerful stimulus to research curiosity. Women who are learning not to accept an argument from authority when it refers to women, who are learning to demand to see the evidence and review and gather it for themselves may, it is hoped, continue to carry these healthy attitudes over into other areas of psychiatry. The result could only be stimulating and beneficial for our field and all of us.

Before about 1970 we saw such remarkable phenomena as an APA Task Force on Psychiatric Aspects of Family Planning that had no women members (84) and the official APA journal that published papers dealing with issues affecting women's lives, such as psychotherapy, family life, abortion, and early child care, but had no women on its editorial board (85). In addition, the published proceedings of a conference sponsored by the National Institute of Health on menopause and aging listed 25 participants, all men (86); clinicians who primarily treated female patients were without formal education or background in women's perceptions of treatment issues; and research site visit committees and review panels often contained no women members. There has been a kind of (often unconscious) arrogance in the willingness of male professionals to tell women how to define their problems and lead their lives and, in parallel, a curious willingness of women to accept male definitions of women's needs. However, today's climate contains some important differences. Since 1967 women have not only had legal rights of equal access to professional education and advancement, but have increasingly felt a sense of responsibility for taking part in the groups and deliberations that define women, whether in research or in clinical treatment.

"Psychology of Women"

"Psychology of women" is a complex concept. The topics previously discussed all pertain to women, but to consider them as constituting a subfield of psychology or psychiatry poses serious theoretical problems. As noted by Parlee (87) in a sophisticated review of issues and research in this area, the term "psychology of women" implies that psychology needs a special set of laws and theories to account for the behavior of women. "The bland assumption that males are more representative of the human race than are females may have created an unknown number of pseudoproblems for psychologists" (87, p. 127). This includes both the failure to detect important and interesting sex differences when they do exist and the failure to refute assumptions about sex differences when they do not exist.

Women are less often subjects in psychological research than are men (88–96). Indeed, in a review of psychological journals one investigator found that female authors were more likely than male authors to have analyzed their data for the presence or absence of sex differences (96). In addition, the question of whether women or men serve as subjects of an experiment tends to depend to some extent on the problem being studied, i.e., studies of aggression are more likely to use only men, while studies of interpersonal attraction contain a higher proportion of female subjects than studies of aggression do. Further, studies are frequently reported and summarized in such a way that findings from those studies conducted on men are generalized to everyone, while results from studies employing women are generalized only to other women.

Generally held assumptions about sex roles or sex differences are often introduced into what purports to be scientific work without the perceived need for supporting evidence. For example, a book reporting clinical research on environmental effects on behavior disorders (97) listed failure to cook her husband's breakfast as ipso facto evidence of pathology in a female patient!

Research findings are likely to be reported or abstracted in biased ways. Male-normative linguistic habits are common and revealing as, for example, in the use of the term "superior" for higher scores by men when "scored higher" was used for higher scores by women (87). It is conventional in research as well as in clinical settings to use generic male terms to refer to persons of both sexes or to positions that could be filled by persons of either sex (e.g., "man and his cities," "chairman" rather than "chair" or "chairperson," and "attending man" for "attending physician"). Available research data (98, 99) indicate that these are not merely neutral linguistic conventions but do have the expected effect of inducing the reader to expect the positions to be filled by a man.

Beyond the use of language there is the problem of inaccurate and/or misleading references to primary data (including the investigator's own data). For example, Asch (100), in discussing the mental and emotional problems of pregnancy, stated that "problems about eating are deeply rooted in the psychology of the pregnant woman" and then cited data that appear to support the opposite conclusion, i.e., an extreme emphasis by clinic staff on avoiding weight gain had been transmitted to patients (avoiding weight gain is now known to be obstetrically contraindicated). Many au-

thors have cited Spitz's (101) and Bowlby's (102) work as shedding light on *maternal* deprivation alone, whereas reading the original reports suggests that sensory and social deprivation were major issues.

Indeed, findings are likely to be explained in stereotyped ways even when support is available for alternative explanations. For example, one study (103) ascribed female toddlers' staying closer to their mother than did male toddlers to "timidity," just one page after noting that mothers had reinforced proximity-seeking in girls while more frequently ignoring it in boys.

Clearly, major biases such as these in the conduct and interpretation of research do not arise by unmotivated accident. An objective and value-free science is a goal rather than something to be consistently expected in real life. Current thinking in the philosophy of science (104), sociology of knowledge (105), and the psychology of effects of expectancy (106) reconfirm our recognition that almost all knowledge has its political and wish-fulfilling contexts. The same point has been made with respect to clinical practice (107, 108). Psychological data about women can be gathered or used in quite different ways, depending on what one wishes to do about women. Henley (109) made a distinction between "psychology of women," "psychology against women," and "psychology for women," pointing to the ways in which data about women can be gathered and used to stereotype women, to "put women in their place," or to be helpful to women.

Literature on the "psychology of oppression" (110, 111) arises from noting the similarity between stereotypical views of women and stereotypical views of other disadvantaged (but sometimes ambivalently envied) groups. Thus women, like blacks, have been described as "inconsistent, emotionally unstable, lacking in a strong superego, weaker or less often healthy, artistic rather than conceptual, nurturant rather than productive, intuitive rather than intelligent . . . if she knows her place she is really a quite lovable and loving creature, happy and childlike" (112, p. 81). Similarly, women are said to be more manipulative, devious, inscrutable, and erratic; it has been accurately pointed out that these are characteristics to be expected from any group that has access to power and economic support only by means of pleasing another, dominant group. An accurate analysis of such stereotypy requires recognition of both true difference (reflecting different coping mechanisms) and perceived but untrue differences (arising from observer bias, lack of knowledge, and/or projective mechanisms).

By contrast, literature on the "psychology of gender roles" arises from noting that there is a division of labor in most human societies which rests in part on reproductive biology and in part on cultural elaboration of the consequences of biological differences. Women are expected to give birth, rear children, feed people, and perform other tasks that a society views as consistent with these responsibilities (whether the individual woman has children or not). Men are expected to perform the residual tasks. Female gender role behavior may then be seen as more firmly grounded in biology (113), with more clarity and "inevitability" or "rightness" attached to it. Male gender role behavior correspondingly is seen as less certain and clear, less biosocially predictable, more subject to change according to social circumstances, more a product of culture, more an achieved than an ascribed status, and perhaps thus for the individual male more of a source of uncertainty, anxiety, and confusion (113, 114).

The role differences between the sexes are often sharply contrasted, often at the price of oversimplification, in the hope of making life simpler or more comprehensible. Clearly defined status and gender roles, where everyone "knows his or her place," are said to be one of the advantages of stratified societies, even when rigid roles result in inequity or blurring of individual differences. On the other hand, fear or envy of prerogatives of the opposite sex, or aggressive or defensive behavior against the opposite sex, is so common as to have received a special term—"the battle of the sexes." There is in fact a long and remarkable tradition of misogynous writings, both scientific and literary, reflecting the fear of women or women's sexuality. This literature has been historically documented by Hays (115), Lederer (116), Rheingold (117), Sherfey (118), Bachofen (119), and others. An attempt to reverse these biases and traditions would constitute a genuine and important scientific revolution.

Scientific revolutions are often, at the beginning, more conceptual than empirical; a new point of view often reorganizes old data before it stimulates the search for new data. The new point of view surfaces in a particular context of scientific and/or political crisis (104) (it is rarely as new as it later appears [120]). It may stimulate anxiety, opposition, and blind discipleship quite as much as it does the objective search for facts.

Thus it has been observed that there were particular resistances to assimilating the work of Copernicus, Darwin, and Freud. The heliocentric model removes our earth from the center of the universe. Evolution makes "man" no longer the species uniquely created to govern this earth. The dynamic unconscious makes "man's" conscious motivation no longer master in "his" own soul.

In this sense the feminist perspective also appears to imply a genuine revolution in social psychology. Man—the male half of the species—is no longer to be viewed as its prototypical member, with female psychology the psychology of the "other," the exception, the supporting cast. In my opinion, the implications of this different perspective will ultimately go far beyond the simple accumulation and assimilation of new data about women.

Directions and Expected Impact of Future Research

We may expect that some applications of some of the current work may be made in ways that in retro-

spect will appear to have been unnecessary or misguided. In particular, the current controversies among biological, social, behavioral, and intrapsychic approaches may be expected to yield, to some degree, to more integrative approaches.

Over the next decade we may expect to see a sustained increase in the number of women involved in psychiatrically related research, as well as research administration and evaluation, thus participating more equally in choosing the topics and determining what studies receive funding.

We should also expect a continued growth in research attention to areas particularly bearing on women's lives. We may hope to see clinical practice related to such areas as women's biosocial psychology, childbirth, childbearing, vocational issues, and marital relationships to be increasingly based on solid research findings rather than the translation into professional language of what is essentially folklore. Appropriate revision of theory should help to increase the sensitivity of our third ears. Better attention to the mental health needs of boys and the effective management of male—and female—aggression in a civilized society may be important aspects of meeting the needs of women and society as a whole.

Until a short time ago it appeared to many that the continued expansion of our industrial society might make the conquest of leisure, and leisure-time personal relationships, the largest social problems for the future. Current ecological and energy crises have clarified some of the limitations of these approaches (121). The "greening of America" (122) no longer appears to be an unlimited, automatic next step. It appears that work will continue to be an important part of the lives of women and men, and the appropriate balancing of work and achievement needs, as well as other personal human needs, will be important issues affecting everyone. This will inevitably be reflected in psychological theory and research and in clinical practice.

"Futurology" is becoming something of a specialty in itself. By definition it is an extrapolation from present research rather than a research field itself. It seems a safe extrapolation to predict a continued advance in the area of women's studies and a greatly increased impact on psychiatry in the near future. This field is so new that we do not as yet have any psychiatric residents who could have had four years of exposure to it as college undergraduates, but the first of that group is now in medical school, and they will be just beginning to enter our residencies in 1978. It should be an interesting decade ahead for all of us.

The Functions and Regulation of the Arousal of Anger

BY RAYMOND W. NOVACO, PH.D.

Anger is paradoxically one of the most talked about but least studied of human emotions. The author presents a model of anger arousal that emphasizes the adaptive as well as the maladaptive roles of anger in terms of the diverse functions anger serves in affecting behavior. In light of the fact that competence in anger management involves dealing with stress situations that require patience, composure, and constructive thought for their resolution, he discusses cognitive self-control processes affecting the regulation of anger.

THERE IS WIDESPREAD CONCERN today about forms of psychosocial stress. As economic frustrations, political mischief, and environmental impairment increase, the arousal of anger is correspondingly found to be a more customary coping response. However, anger, although one of the most talked about human emotions, is the least studied. Aggression and violence have been prominent topics in behavioral research, but anger arousal has received considerably less attention. As Rothenberg (1) stated, "Almost invariably, anger has not been considered an independent topic worthy of direct investigation but has been subsumed under a general category such as aggression, emotion, or affect."

The arousal of anger, in an elementary sense, can be viewed as an emotional response to provocation that has identifiable autonomic (2), central nervous system (3, 4), and cognitive (5–7) components. Whether or not anger leads to aggressive behavior depends on the magnitude and appraisal of the provocation, situational constraints, expected outcomes, and the person's preferred style of coping. Although the physiological characteristics of anger are of important theoretical concern, anger will be discussed in this paper as a subjective affect. In an effort to further the investigation of anger, a functional model of anger arousal will be presented along with a discussion of cognitive processes that have an effect on anger regulation.

There has been some discussion as to whether anger is a primary or a secondary emotion. Because anger has been shown to arise in response to ego threat or insecurity, anxiety is claimed as the more basic emotion (1, 8, 9). In discussing parent-child relationships, Gordon (8) asserted that anger is an emotion that is manufactured by the parent as a consequence of primary feelings such as fear, embarrassment, or disappointment.

The question of whether anger is a primary emotion or an emotion secondary to anxiety is largely a pseudoproblem. The arousal of anxiety is at times undoubtedly associated with the arousal of anger. Fear stimuli elicit anger as a defense, but whether this is exclusively the case is unfounded in evidence or theory. The functional model presented below accounts for the defensive role of anger as well as a related potentiating function whereby anger serves as a means to induce the experience of personal control.

The relationship between the arousal of anxiety and the arousal of anger is by no means a simple one. Cognitive and contextual factors are important determinants of how emotional arousal is experienced and labeled. Lazarus (5) argued that one's response to threat is largely determined by cognitive appraisal. This was reflected in Schacter and Singer's classic experiment (6), which demonstrated that information and social circumstances affect whether arousal is labeled as anger. Rational-emotive therapy (10), Meichenbaum's procedures for anxiety-based problems (11), and my own procedures for chronic anger problems (7) are each predicated on the idea that emotional states are defined or determined by one's cognitive structuring of a situation.

Provocation experiences consist of interrelated, sequential components. Although anger as an affective state is distinct from aggressive behavior, the experience of anger is nonetheless influenced by the course of action taken in response to provocation. According to the James-Lange theory (12), the emotion that one experiences is a function of one's overt behavior in the situation. Arousal will more probably be construed as anxiety if the person withdraws from or avoids the provocation and as anger if he or she challenges or approaches. In another sense, whether one experiences anxiety or anger is a function of one's coercive power relative to the provoking person. As the perception of personal control diminishes, the arousal of anxiety during a provocation has an increased probability. Indeed, as the presentation below stipulates, the arousal of anger can be evoked to generate a sense of personal control.

The common confusion of anger with aggression and hostility has blurred the recognition of anger's adaptive functions. The consequence is that anger is equated with destructive forces. In the model of anger

Dr. Novaco is Assistant Professor of Social Ecology, University of California, Irvine, Calif. 92717.

arousal presented here, the energizing, expressive, discriminative, and potentiating functions make it clear that anger can have very beneficial effects.

ANALYSIS OF ANGER FUNCTIONS

Paradoxically, anger is both satisfying and frightening. Although anger is often thought of as something to be controlled, one difficulty in the treatment of persons with chronic anger problems is that they may enjoy getting angry. Although our anxieties about anger arousal follow from expectations of subsequent aggression or of social censure, the satisfaction associated with anger derives from the fact that anger serves important positive functions in coping with stress.

Energizing Functions

One of the most recognizable functions of anger arousal is that it energizes our behavior. Anger increases the vigor with which we act. This can result in strong motor responses, such as slamming doors or raising the volume of one's voice. This energizing effect can also enable a person to assertively confront provocation or injustice. Nearly all social movements have anger as a driving force for efforts at social change. Certainly there is no other emotion that better characterizes the women's movement for equal rights. The Chinese word for anger is *sheng ch'i*, meaning to produce one's *ch'i*, which is the word for energy.

Disruptive Functions

However, as an arousal state that raises the amplitude of response systems, anger can have a disruptive effect on behavior. When arousal is high, anger interferes with efficient task performance. Cognitive processes become disorganized, and reactions become impulsive. A child-abusing parent, for example, will be irritated by some behavior of the child, fail to understand the situation in terms of age-appropriate behavior, and overreact with physical force. When people are agitated, they often act before they think. Competence in anger management represents personal effectiveness in dealing with stress situations that require patience, composure, and constructive thought for their resolution.

Expressive Functions

It is well known to marital counselors that anger serves important expressive or communicative functions (1, 13). Frustrated expectations lead to smoldering anger, which disrupts intimate relationships. A healthy relationship depends on the ability of partners to express anger and give one another negative feedback. Some problems never reach the discussion stage until one member of the relationship becomes demonstrably angry. Bach and Wyden (13) addressed these problems in communication between intimates and developed a system that trains lovers to be effective fighters. Interpersonal problems arise from the manner in which people express their anger or what they do when becoming angry. Because of anger's disruptive components, people often need help in expressing negative feelings in a way that will resolve conflict rather than merely escalate a sequence of antagonism.

Self-Promotional Functions

A more subtle form of social communication consists of impression management. The irascible individual is a master of dramaturgy in the presentation of self. Goffman's thesis (14) is that when a person is in the presence of others he will organize his actions in such a way that they convey an impression of himself that is in his interest to convey. In this context, anger arousal has a self-promotional function. When one is thwarted or stressed, it is often preferable to take the role of an angry, agitated person rather than to be seen as someone who is anxious, apprehensive, or apathetic.

As a performer, the angry person is claiming qualities and attributes that are socially valued. The demonstration of anger advertises potency, expressiveness, and determination. Although someone's manner may be truculent and thereby looked on with disdain, he or she is nonetheless defining or even demanding how others are to relate to him or her. The demonstration of anger can thus be seen as a strategic move to foster and protect one's public image. A prototypical case is the pronounced indignation of a public official in addressing matters of consequence.

Among the character types discussed by Toch in the classification of violent personalities (15) are individuals who use self-preserving strategies to enhance their image in the eyes of others. Just as proneness to aggressive behavior can be seen in terms of a concerted effort at building a reputation, the demonstration of anger can be seen as an orchestration to promote an impression of oneself to a particular audience. When one's manner of expression is eruptive, the impression of a volatile individual who should be kept at arm's length is fostered. A performance of suppressed rage with some telltale signs of annoyance invites antagonism that can then be used against the other person. In contrast, the demonstration of anger that addresses issues and tasks rather than attacks another's self-worth pulls for a response that can lead to constructive resolution of conflict.

Defensive Functions

As suggested earlier, anxiety is implicated in the arousal of anger. Its involvement can be fruitfully understood in terms of a defensive function. "Defensive" here refers to ego defense, whereby anger occurs as a not-so-necessary protective reaction to feelings of vulnerability. Anxious feelings of vulnerability are short-circuited or preempted by the arousal of anger. It is less distressing to be angry than to be anxious. Anger externalizes the conflict by directing attention to something that is nonself: "There is nothing wrong with me; there is something wrong with you."

Clinical observations in the interactional arena of psychotherapy have recognized this role of anger. Sullivan (16) remarked on this defensive process:

> Thus when another person seems annoyed or angry, we are most likely to approach a simple understanding of the situation if we ask ourselves whether what we did had in some way impaired his security, so that the anger was called out merely as an avoidance of the anxiety that would otherwise have been aroused. . . . Anger blunts the feeling of personal insecurity (p. 96).

On a larger social scale, Halleck (17) claimed that people use violence to combat or prevent feelings of helplessness from reaching levels of conscious awareness.

Potentiating Functions

Closely related to the defensive role of anger is the extent to which it potentiates a sense of personal control or of being in charge of a situation. Anger arousal induces a sense of potency. The relevance of belief in personal control to psychopathology, accommodation to stress, and psychotherapy has been well documented and reviewed by Lefcourt (18, 19). Correspondingly, anger can be more effectively regulated if one perceives himself or herself as competent to handle provocation (7).

The anger that is observed among ardent members of social movements develops as a reaction to the experience of powerlessness and results in the mobilization of resources. As one begins to see his or her social status in terms of oppressive social forces rather than in terms of personal and moral weakness, alienation is transformed into anger. This conversion of affect can facilitate the attainment of personal goals and even social change. As Melges and Harris (20) stated, "The feeling that one has little control over his own destiny may lead to attempts to restore oneself as an active agent. This may involve attacking those who appear to be influencing and controlling the individual."

To the extent that anger arousal directs us toward constructive action and problem resolution, its adaptive value in this potentiating role is transparent. The danger is that anger is sometimes aroused in a blind effort to assert with force. As Rothenberg stated (1), "If we think of hitting someone or even killing someone, we feel far more powerful and in control of the situation than if we think of fleeing or doing nothing." Psychotherapy for chronic anger must therefore impart to the client a set of nonantagonistic skills for coping with provocation.

Instigative Functions

As an emotional response to provocation, the arousal of anger and the cognitive processes associated with that arousal (i.e., thoughts about the provoking person and the thwarting situation) can instigate aggressive actions. The admixture of agitation, thwarted expectations, and hostile internal dialogue serves as a cumulative stimulus for aggressive behavior. There is a learned connection between anger and aggression. An aggressive act is expected to change the situation or conditions that have provoked anger. Experimental studies of aggression in laboratory settings standardly use this function of anger; insult conditions are manipulated to elicit aggressive acts by the subject.

Discriminative Functions

Although the arousal of anger constitutes a state of agitation or tension, awareness of anger can be trained to function as a discriminative cue. Attunement to the signs of anger can alert one to the psychological significance of a situation and serve as a cue to use coping strategies that will be effective in resolving conflict. The concept of affect as a signal has been part of psychoanalytic theory, but this idea is more often applied to the emotion of anxiety. In a previous study (7) clients were trained to use anger as a cue for nonantagonistic coping strategies. This signal function of anger has also been discussed by Melges and Harris as part of a cybernetic model (20) and by Solomon in recommending mechanisms for the control of hostility (21).

THE REGULATION OF ANGER

Virtually every form of psychotherapy that construes behavior in terms of dynamic processes has emphasized the recognition and expression of affect. The underexpression of anger has also been a focal concern of assertion training (22), which has blossomed in popularity among behavior therapists.

Although suppressed anger is easily addressed by a variety of psychotherapies, the overexpression of anger has been a more refractory problem. Reich's concept of character armor (23) is indeed applicable to chronically angry and assaultive persons, who have typically been among the most difficult of clinical populations. The classic treatment of this population has consisted of facilitating increased ego controls. For example, Redl and Wineman's work with "children who hate" (24, 25) was directed toward the improvement of frustration tolerance, impulse control, the capacity to love, and self-corrective mechanisms.

Recently, I demonstrated that cognitive self-control procedures can be designed to regulate anger arousal (7). Cognitive coping procedures were particularly effective when combined with training in relaxation. The cognitive coping skills involved in the treatment of chronic anger consisted of the following: 1) education about personal anger patterns, 2) self-monitoring of anger arousal and its cognitive companions, 3) the ability to alternatively construe provocation, 4) covert self-instruction to guide one's appraisal of events and to cue nonantagonistic responses, and 5) the ability to remain task oriented rather than ego oriented when provoked. These interventions were designed to impart a sense of personal control in the management of provocation.

The basic steps in the method of treatment consisted of cognitive preparation, skill acquisition and rehearsal, and application of coping techniques. It is similar to a procedure called "stress inoculation" that Meichenbaum and Cameron applied to anxiety problems (26).

Cognitive Preparation

Beginning with an extensive discussion of personal anger patterns, a situation analysis of proneness to provocation was obtained. Clients were asked to keep a diary of their anger experiences. This enabled them to develop self-monitoring skills and to assess the relative magnitude of anger reactions. The influence of cognitive processes on emotional arousal was stressed, and emphasis was placed on perceived threat to self-worth, wanting to be in control of a situation, and acts of antagonism that escalate the anger episode. Clients were directed to become aware of anger-instigating thoughts as well as the somatic tension often associated with provocation. Because tension and relaxation are incompatible, learning to relax was presented as a way to regulate anger.

Skill Acquisition and Rehearsal

Clients were encouraged to discriminate circumstances for which anger is justified from those for which it is less desirable and even harmful. As in rational-emotive therapy (10), they were reminded that it is not events themselves that provoke anger but their constructions and beliefs about those events. As a way to change their cognitive templates of provocation, they were provided with a package of self-statements that would facilitate anger regulation. This set of self-statements was designed so that it could be applied to provocation experiences when viewed as a sequence of specified stages. The cognitive procedures thus allow for self-controlled intervention at various points of the provocation sequence.

One of the most effective ingredients of the treatment program was learning how to remain task oriented or problem focused in an anger-arousing situation. Becoming task oriented has several adaptive effects in the face of provocation: 1) the person begins to define the situation in terms of a problem that calls for a solution instead of a threat that calls for attack, 2) by attending to the issues of an argument, the person avoids responding in ways that escalate the anger sequence, and 3) by focusing on the issue or task, the person directs his attention away from internal stimuli (cognitive and physiological) that are associated with anger. As a complement to the cognitive techniques, clients were instructed in relaxation skills using the Jacobsen method of systematically tensing and relaxing a series of muscle groups (27). Various forms of mental imagery and additional emphasis on breathing techniques were used to assist relaxation induction.

Practice and Application

The practice of coping techniques was achieved by using a hierarchy of provocation items prepared by each client. The hierarchy consisted of a graduated series of provocations that they were likely to experience on a day-to-day basis. Using an imaginal presentation of hierarchy scenes, clients practiced relaxation and personally generated self-statements to cope with arousal. Their anger diaries also provided a log of provocation experiences and their relative proficiency at anger management. Following treatment, clients were challenged with the application of their coping skills in imaginal, role-play, and direct provocation conditions (7).

In addition to cognitive coping and relaxation skills, persons with chronic anger problems need to acquire behavioral strategies for responding nonantagonistically to provocation. The task-oriented set is so designed; it can be augmented by facilitating responses that are incompatible with hostility, such as empathy and compassion. The ameliorating influence of empathy and nonantagonistic communications has been emphasized by Feshbach and Feshbach (28, 29).

The ability to manage internal arousal states and to adapt to stress events has become an increasingly necessary psychological skill. It is hoped that therapeutic processes for the regulation of uncontrolled anger will receive further research attention. I have proposed some directions for that research in the areas of essential hypertension and child abuse (7). At the same time, mental health professionals must recognize the many adaptive functions of anger that can be mobilized in the attainment of treatment goals.

A Reconsideration of the Kety and Associates Study of Genetic Factors in the Transmission of Schizophrenia

BY LORNA S. BENJAMIN, PH.D.

The author reviews a study by Kety and associates that reported a significantly greater prevalence of schizophrenic spectrum disorders among the biological relatives of schizophrenic adoptees than among those of nonschizophrenic adoptees. The principal statistical analysis of the Kety study used an incorrect sample size (306 rather than 66) and failed to weight each index and control case (family) equally. This violation of the independence assumption would allow a few families to disproportionately influence the outcome. The author argues that proper statistical analysis applied separately to available categories indicates that significant differences between the index and control groups occurred mainly in the half-sibling category; this result violates the principle that genetic effects increase with greater consanguinity. She concludes that Kety and associates' study raises more questions than it answers regarding the role of genetic factors in schizophrenia.

EXTENSIVE EFFORTS have been devoted to determining whether and to what degree genetic factors are involved in the transmission of schizophrenia. Lacking the direct chromosomal evidence available in such diseases as Down's syndrome, investigators of schizophrenia have turned largely to the indirect method of statistical analysis of prevalence in populations that vary in degree of consanguinity and degree of environmental similarity. Such efforts are often frustrated by confounding of experiential with genetic factors, i.e., persons who are similar genetically also tend to be raised in similar environments. Instances in which persons with similar genetic heritage are raised in different settings are seized upon as a means of separately identifying genetic and environmental influences.

The most carefully controlled, frequently cited investigation of this sort was conducted by Kety, Rosenthal, Wender, and Schulsinger, who provided an exhaustive report of their original work in a volume edited by Kety and Rosenthal (1). The highlights of this study, which contrasted institutional records of prevalence of schizophrenia in biological families of schizophrenic adoptees (index group) with prevalence of schizophrenia in biological families of adoptees without psychiatric history (control group), were also published later in this journal (2). Recently a follow-up study based on interviews in addition to the institutional records has appeared (3).

All three publications reported significantly more relatives with schizophrenia in the index group of adoptees and concluded that a strong link between genetic factors and transmission of schizophrenia had been demonstrated. Results were interpreted in terms of an "illness" model in which schizophrenia is hypothesized to be analogous to diabetes mellitus (3, p. 164). This illness model includes biochemical and somatic factors inferred from the genetic findings; it also includes the possibility of psychological factors coming from environmental influence.

This paper is not intended to take a position for or against the argument supporting the role of genetic factors and/or biochemical "illness" components in schizophrenia. Rather, it is intended to correct the record. When proper statistical analysis is applied to the Kety and associates data, the significant contrasts obtained do not provide convincing support for the authors' broad claim that "genetic factors operate significantly in the transmission of schizophrenia and . . . the higher than expected prevalence of schizophrenia in the families of naturally reared schizophrenics is a manifestation of such transmission" (2, p. 304). The authors' conclusions are premature and their findings raise more questions than they answer. The environmentalist and the geneticist are equally disadvantaged in accounting for the peculiar group differences actually obtained.

DESIGN AND METHOD OF THE STUDY

The original study of Kety and associates was distinguished by the extent of its efforts to control confounding of genetic and environmental variables. The investigators identified and categorized subjects by searching the extensive and complete population register of Denmark, adoption records, the Psychiatric Register of Denmark's Institute of Human Genetics, the records of hospitals, police, the military, and the records of the Mother's Aid Organization. The categories of chronic schizophrenia, acute schizophrenia, borderline schizophrenia, possible schizophrenia, and inadequate personality were included as representing

Dr. Benjamin is Associate Professor, Department of Psychiatry, University of Wisconsin—Madison Medical School, 1300 University Ave., Madison, Wis. 53706.

the schizophrenic spectrum disorders; 33 adoptees with records of psychiatric hospitalization were cast into the index group by independent judges reading English-language abstracts of Danish psychiatric histories. Thirty-three controls from the same national pool of 5,483 adoptees were matched to the index cases for sex, age, socioeconomic class of the adoptive parents, time spent with the biological family, and preadoption history. The controls differed from index cases in that they had no known psychiatric history. The investigators then searched the records to locate all possible biological and adoptive parents, siblings, and half-siblings for each index and control case. Judges independently determined whether or not schizophrenia was present or absent in these relatives.

RESULTS AND DATA ANALYSIS

The principal findings of this study (2, p. 304) are reproduced in table 1. Data in the first column of table 1 were reported by the authors as being significant at the .0072 level. Of the 150 biological relatives identified for the index cases, 13 were classified as having schizophrenic spectrum disorder. For the control adoptees, 156 relatives were identified; 3 of these were classified as having schizophrenic spectrum disorder. These data indicate that 8.6% of the biological relatives of the index schizophrenics also had schizophrenia, whereas only 1.96% of the biological relatives of adoptees without psychiatric history had a schizophrenic spectrum disorder. Comparisons of the prevalence of illness in biological and adoptive relatives were appropriately ignored since adoptive families are screened for health.

The particular statistical test used in comparing biological relatives of index and control groups was not mentioned, but it was probably a chi-square test applied to the data from column 1 of table 1 as they are re-presented in table 2. The outcome of a chi-square test applied to this 2×2 contingency table using the correction for continuity is 5.73, which is significant at better than the .0025 level. The authors apparently used Fisher's exact test to get the .0072 level reported.

An analysis of table 2 implies that 306 cases have been independently cast into one of the four cells in the table and the statistically significant result reflects differences in frequencies entered in the cells over and above the baseline rates represented by the marginal entries. The row marginals give different weights corresponding to (potentially) different group sizes. The column marginals give different weights corresponding to overall base rates of schizophrenia independent of group membership. Table 2 suggests that 13 schizophrenics were found in the joint classification that indicates index group membership and having a schizophrenic relative, whereas only 7.84 instances would be expected on the basis of independent marginal estimates. Similarly, only 3 cases were found in the joint classification indicating control group membership and having a schizophrenic relative, whereas 8.16 would be

TABLE 1

Prevalence of Schizophrenic Spectrum Disorders Reported by Kety and Associates (2) Among Biological and Adoptive Relatives of Schizophrenic and Nonschizophrenic Adoptees

Sample	Prevalence of Schizophrenia	
	Biological Relatives	Adoptive Relatives
Index cases (N=33)	13 of 150	2 of 74
Control cases (N=33)	3 of 156	3 of 83
Significance	p=.0072	n.s.

Implied Logic of Kety and Associates' (2) Statistical Analysis of the Prevalence of Schizophrenia Among Biological Relatives of Schizophrenic and Nonschizophrenic Adoptees

Sample	Biological Relatives		
	Schizophrenic	Not Schizophrenic	Total
Index cases (N=33)	13	137	150
Control cases (N=33)	3	153	156
Total	16	290	306

expected on the basis of marginal estimates. These represent 66% ([13–7.84]/7.84) and 63% ([3–8.16]/8.16) deviations from expectation and do indeed seem "significant."

Sample Size and Weighting

However, table 2 does not in fact describe or correspond to the experimental procedure, and it violates the independence assumption (reviewed in reference 4, pp. 395–398; a theoretical background appears in reference 5, pp. 204–209). The 66 individuals presented in the study should be independently classified in the 2×2 form of table 2. Not only is the sample size 66 instead of 306, but there is also a confounding of genetic and environmental factors. Each index case should have a weight of 1/66 (or 1/306, if 306 had been the legitimate sample size) in the total analysis. The procedure of counting up all the possible relatives of each index case and pooling them as if they were independent samples (to give an N of 150 as shown in table 2) would allow some families to disproportionately affect the results. For example, index cases with more than 1 schizophrenic relative could unduly weight the cell in the first row, first column of table 2. This group of people, who were likely to have been reared together and to have had the same health care system supplying information for the records used in the study, could falsely inflate the "significance" of the difference.

Table 1 was the only analysis presented in the journal paper (2) that summarized the highlights of the original study. The problem of disproportionate contributions from particular families was acknowledged in the follow-up report (3, p. 156), but the proper analysis based on an N of 66 was not consistently applied even in this paper. The inflated N was used for most tables

presented. Even more curious was the fact that the proper analysis (using N=66) was reported in a sentence in the text of the first paper (1, p. 356), and differences between index and control families were in fact significant in the expected direction.

It would be nice to let the matter rest with the observation that, although the authors violated the independence assumption in many of their analyses, when the proper analysis was applied the critical difference between index and control subjects was significant in the expected direction, so their conclusions should stand. However, on taking a closer look at the index-control group differences, a new problem emerges.

Significance and Degree of Consanguinity

Table 3 presents the number of index and control families (N=66) having schizophrenia, by degree of consanguinity. The top section of the table reports the results of the original institutional records study (1). The bottom section reports results of the second, more questionable study, which added relatives defined as schizophrenic on the basis of one interview conducted by an author whose impressions were independently judged by other authors reading transcripts edited for reference to consanguinity (3). In both studies there was a highly significant difference between index and control groups in the half-sibling category, and there were no clear differences in the full-sibling or parent categories. This finding is peculiar and contradictory. It shows, in effect, that the *less* the consanguinity, the *greater* the "genetic" effect. Differences should be weakest, not strongest, in the half-sibling category. The authors discount this contradiction by noting that there were few siblings located for these adoptees. Indeed, in the original study there were only 2 index families and 4 control families that yielded any full siblings at all. By contrast, there were 25 index families and 28 control families having half-siblings. A chi-square analysis taking these differential Ns into account would use the numbers of families having persons in the category being studied. This would yield family sample sizes of 2 and 4 for index and control groups, respectively, in the sibling matrix. The procedure would use family sample sizes of 33 and 32 in the parent category, and Ns of 25 and 28 for families in the half-sibling category. The significance of the findings reported in table 3 does not change when this procedure allowing for differential Ns is applied to the data in the original study. (Not enough information is available to apply it to the follow-up study, which added schizophrenia diagnosed on the basis of one interview.)

Fisher's exact test is the only alternative for analysis of the sibling category using sample sizes of 2 and 4, and the resulting significance level (p=.93) emphasizes how weak the contrast is in such a small sample. It is clearly reasonable to argue, as did the authors, that too few siblings were available to give a useful contrast between index and control subjects in the sibling category. However, the fact remains that the sampling of parents was nearly complete; in fact, both parents were located in 90% of the index families and in 94% of the control families. If there is an unequivocal genetic effect, the differences between index and control groups must be greater in the parent category than in the half-sibling category. Table 4 reviews the basic genetic logic behind this suggestion.

If one parent represents gene pool [a] and the other parent gene pool [b], then their children (sibling category) would have 50% sampling from gene pool [a] and 50% from gene pool [b]. A survey such as that conducted by Kety and associates invokes a logical .OR. condition (i.e., tallies yes if one or both conditions are met) for the parent category, since either a schizophrenic mother or father was accepted in the tally. Un-

Child of A and B	[½(a,b)]
Child of A and X or	[½(a,x)] or
child of B and X	[½(b,x)]

*Each bracket describes the gene pool for one individual. The elements of the vector within each bracket total 1, accounting for 100% of each person's genes.

der this procedure, and using an analysis that allows for different sample sizes, differences between index and control subjects should be comparable for the parent and sibling categories. In other words, a sample of both parents includes gene pools [a] plus [b], as does a sample of siblings. A sample of half-siblings, however, taps gene pools [a] and [b], plus gene pool [x] from the new parent. The two categories from gene pools [a] and [b], namely parents and siblings, should show a larger, not a smaller, difference between index and control groups. The fact that a third category, which included a different gene pool, accounted for the difference between index and control cases precludes a straightforward genetic interpretation of the results.

Matching for Socially Adaptive Attributes

Before speculating on the meaning of the difference between half-siblings of index and control groups, it is important to first clarify some general methodological issues relevant to all comparisons of index and control groups. Although the interpretive assumption of the authors was that differences are associated with poor (destructive, defective, illness-inducing) genes in the index group, it is equally possible that observed differences could also be associated with good (constructive, superior) genes in the control group. For example, those who think of schizophrenia as a maladaptive social solution to problems in living might argue that the control adoptees without any psychiatric history had more genetically determined social assets, such as better physical appearance, intelligence, athletic ability, and/or other talents that can facilitate optimal social adjustment in Western culture.

Since it has been clearly established that these socially adaptive attributes have genetic links, those who argue that schizophrenia relates importantly to social adaptation would require, before accepting contrasts as indicative of a destructive "illness" gene, that the index and control groups be matched on these and related variables in the *biological* as well as in the adoptive families. Since no matching of any sort was reported for the biological families, it may not be possible to properly interpret the findings of the Kety and associates survey no matter how much additional information can be brought to bear. (The authors indicate that they plan to publish still more analyses of their sample [3, p. 157].) Since the study failed to match the biological families of index and control groups for genetically based social assets, it could be that control adoptees without psychiatric histories tended to come from middle- and upper-class persons with favorable genetic heritage who were giving up infants for adoption because of illegitimate teenage pregnancies, whereas index adoptees tended to have been put up for adoption because of more chaotic social situations characteristic of persons with less genetic (and environmental) advantage in social adaptation. However, this formulation, like the genetic interpretation, falters because of the failure to find differences between the index and control parents.

Thus the argument remains at a stalemate. A small sample of 66 adoptees yielded an unusual but understandably high proportion of half-siblings, and significantly more half-siblings of the index group had schizophrenia. However, the failure to find differences between index and control parents challenges both the simple genetic illness and genetic social advantage interpretations of the data at hand. Nor does a consistent environmental interpretation of the peculiar findings come to mind.

CONCLUSIONS

It is reasonable to hypothesize that there is an interaction between genetic and environmental factors in schizophrenia. The Kety and associates data do not help establish whether the correct model is the illness model of diabetes mellitus or whether schizophrenia reflects an interaction between genetics and social learning analogous to that presumed to operate in the development of intelligence. (Assume, for the sake of argument, that there is in fact agreement about the models for diabetes mellitus and for intelligence.) Whatever the appropriate model, it is clear that specific studies of biochemical contributions to human behavior remain a high priority. It is equally important to continue to develop better understanding of how to arrange environmental conditions for optimal social development and of how to provide effective corrective social learning experiences in cases in which development has aborted. The current data do not suggest that the biochemical approach has priority over the social approach or vice versa. Even if the results had been less equivocal, one would still worry about the potential usefulness of this particular approach to the question of the role of genetics in schizophrenia. The pitfalls of generating "definitive" models of human function on the basis of simple statistical contrasts are aptly noted by Feldman and Lewontin (6), who reviewed the recent controversy over genetics, intelligence, and race. They concluded:

At present, no statistical methodology exists that will enable us to predict the range of phenotypic possibilities that are inherent in any genotype, nor can any technique of statistical estimation provide a convincing argument for a genetic mechanism more complicated than one or two Mendelian loci with low and constant penetrance. Certainly the simple estimate of heritability, either in the broad or narrow sense, but most especially in the broad sense, is nearly equivalent to no information at all for any serious problem of human genetics. (6, p. 1168)

Studies Designed to Disentangle Genetic and Environmental Variables in Schizophrenia: Some Epistemological Questions and Answers

BY SEYMOUR S. KETY, M.D.

The author addresses questions raised by Dr. Lorna S. Benjamin in the preceding paper. He quotes from the original studies to respond to questions regarding statistical logic, the relative prevalence of schizophrenia among half-siblings and parents of index adoptees, and the possible role of socioeconomic status as a confounding variable.

THE RESEARCH that David Rosenthal, Paul Wender, Fini Schulsinger and I have carried out with a number of associates over the past 14 years on a total sample of adopted individuals and their families has aroused some interest and comment, not all of it as critical as that found in the preceding paper. This response will attempt to answer the questions Dr. Benjamin raises. Many have been answered in the papers she criticizes but may not have read very carefully. Thus:

> *Dr. Benjamin:* The particular statistical test used in comparing biological relatives of index and control groups was not mentioned . . .
>
> *Our paper:* The difference is highly significant (p, one sided probability from exact distribution=0.0072). (1, p. 353)
>
> *Dr. Benjamin:* The principal statistical analysis . . . used an incorrect sample size (306 rather than 66) and failed to weight each index and control case (family) equally, [which] . . . would allow a few families to disproportionately influence the outcome.
>
> *Our paper:* By examining the distribution of schizophrenia spectrum disorders in the biological families and taking family size into consideration, no evidence is found to support the thesis that the high prevalence in the relatives of index cases derives from a few deviant families. The 13 such relatives of the total index sample come from 9 families, the 9 relatives with schizophrenia spectrum disorders among the early transferred cases represent 6 families, and the frequency of affected biological families in each sample of index cases (9/33 or 6/19) is significantly higher (p=0.028 or 0.012) than the frequency of affected families for the corresponding control groups (2/32 or 0/19). (1, p. 356)

Dr. Kety is Professor of Psychiatry, Harvard Medical School, and Director, Psychiatric Research Laboratories, Massachusetts General Hospital, Fruit St., Boston, Mass. 02114.

> *Our paper:* We have dealt up to this point with these relatives as individuals; as a matter of fact, they are members of families and it is probably not entirely appropriate to perform statistical analyses using the degrees of freedom represented by the individual relatives when these are clustered into a limited number of biological and adoptive families. Therefore, we have also analyzed these data in terms of families. (2, p. 156)
>
> Tables 4a and 4b give the distribution of definite and uncertain schizophrenia in the biological and the adoptive families of the index cases and the controls for those probands who have at least one such diagnosis among their biological or adoptive family. Whereas the number of adoptive families with at least one such case is relatively small and not significantly different for index vs. control probands, more than half of the biological families of the index cases (17/33) show one or more definite or uncertain schizophrenias as compared with 5 of 34 biological control families and only one biological family of the 23 "screened" controls. There are significant differences in this regard between the index families and the combined control families (p=.0014) or the "screened" control families (p=.00013). [Footnote, p. 154: p in this and other tables refers to Fisher's exact probability.] (2, p. 156)

However, our conclusions regarding the operation of genetic factors in schizophrenia were not supported by these findings alone, even though they were obtained using the statistical logic Dr. Benjamin requires; we also pointed out that

> This evidence is compatible with a genetic transmission for schizophrenia, but it is not entirely conclusive, since there are possible environmental factors such as *in utero* influences, birth trauma, and early mothering experiences which have not been ruled out. One cannot, therefore, conclude that the high prevalence of schizophrenic illness found in these biological relatives of schizophrenics is genetic in origin. However, the largest group of relatives which we have is, understandably, the group of biological paternal half-siblings. Now, a biological paternal half-sibling of an index case has some interesting characteristics. He did not share the same uterus or the neonatal mothering experience, or an increased risk of birth trauma with the index case. The only thing they share is the same father and a certain amount of genetic overlap. Therefore, the distribution of schizophrenic illness in the biological paternal half-siblings is of great interest . . . (2, p. 156)
>
> There are 63 biological paternal half-siblings of index cases and 64 paternal half-siblings of controls, which have

between them 16 individuals diagnosed by records or interviews as definite or uncertain schizophrenia. There is, however, a highly unbalanced distribution; 14 are among the half-siblings of index cases and only 2 in the controls ($p=0.001$). [When these results are analyzed by probands as Dr. Benjamin's logic requires, we find 10 schizophrenic adoptees with definite or uncertain schizophrenia in biological paternal half-siblings compared to 2 control adoptees ($p=.01$)] . . . We regard this as compelling evidence that genetic factors operate significantly in the transmission of schizophrenia. (2, p. 156)

SCHIZOPHRENIA IN HALF-SIBLINGS AND PARENTS

In the second half of her paper, Dr. Benjamin concedes that her statistical analysis *was* applied in our publications, but now raises another objection:

> . . . when the proper analysis was applied the critical difference between index and control subjects was significant in the expected direction, so their conclusions should stand. However, on taking a closer look at the index-control group differences, a new problem emerges . . . . In both studies there was a highly significant difference between index and control groups in the half-sibling category, and there were no clear differences in the full sibling or parent categories. This finding is peculiar and contradictory. It shows, in effect, that the *less* the consanguinity the *greater* the "genetic" effect.

The last sentence is an improper inference, drawing a conclusion that statistical logic does not permit. There were, in fact, 13 index probands with diagnoses of definite or uncertain schizophrenia in one or more of their half-siblings and 8 index probands with such diagnoses in their biological mother or father; the difference between these numbers is not statistically significant and does not justify a statement that one is higher than the other. Let us assume, however, that we had made significantly more diagnoses of schizophrenia in half-siblings than in parents; would that in fact contradict genetic logic? It would do so only if one thinks of genetics in the most simplistic terms and fails to take into consideration the socioenvironmental selective factors that confound the distribution of genes in a human population and the problems of ascertainment of human disease.

Epidemiological studies in large populations have always found a low prevalence of schizophrenia in the parents of schizophrenics. Slater (3), summarizing 25 independent investigations, cited a combined expectation of 3.8% in parents, 8.7% in siblings, and 3.2% in half-siblings. This deficiency of schizophrenia in parents has been adequately explained on the basis of the demonstrated reduced fertility of overt schizophrenics. In the case of our sample there are additional social factors that significantly reduce the likelihood that a schizophrenic will become the parent of a child put out for adoption:

> The enlightened social system in Denmark makes it possible for a pregnant woman to obtain a legal abortion on the basis of a history of schizophrenia in herself or in the father. This, in addition to the relative infertility of overt schizophrenics, could have resulted in the removal from our sample of adoptees of a disproportionate fraction of those with schizophrenia in the biological parents. If, in a similar manner, the adoption process screens out children born of parents with known schizophrenia, this would further have contributed to the possible impoverishment in our adoptee sample of potential index cases with an established incidence in their biological families. (1, p. 360)

In addition, there are many factors that reduce the likelihood of making a diagnosis of schizophrenia in a parent as opposed to a half-sibling in our sample. More than twice as many index biological relatives had died than had their controls. This excess included five suicides, all of which occurred in the index biological parent group. Since it is well known that suicide is an unfortunate outcome for many schizophrenics, it is likely that this in itself depleted the sample of some schizophrenic biological parents. Because of these and other deaths among the parents, who constitute an older population, only 45% of the biological parents were interviewed, as contrasted with 83% of the half-siblings. All of the factors enumerated above, each of which would have the effect of reducing the ascertained prevalence of schizophrenia in our sample of biological parents, make it difficult to agree with the premise "that the sampling of parents was complete," or with the conclusion based on that premise that our results are incompatible with genetic principles.

SOCIOECONOMIC STATUS CONSIDERATIONS

Dr. Benjamin levels still another criticism at these studies and proposes a hypothesis that was entertained, examined, and rejected in one of our previous publications (4).

> *Dr. Benjamin:* Those who argue that schizophrenia relates importantly to social adaptation would require, before accepting contrasts as indicative of a destructive "illness" gene, that the index and control groups be matched on these and related variables in the *biological* as well as in the adoptive families. Since no matching of any sort was reported for the biological families it may not be possible to properly interpret the findings of the Kety and associates survey no matter how much additional information can be brought to bear. (The authors indicate that they plan to publish still more analyses of their sample). Having failed to match the index and control groups of biological families, it could be that control adoptees without psychiatric histories tended to come from middle- and upper-class persons with favorable genetic heritage who were giving up infants for adoption because of illegitimate teenage pregnancies, whereas index adoptees tended to have been put up for adoption because of more chaotic social situations characteristic of persons with less genetic (and environmental) advantage in social adaptation. [Dr. Benjamin did not know that only 3 of the index adoptees and 4 of the controls were born of married couples.]

> *Our paper:* If there is a relationship between social class and psychopathology, how may it be interpreted? Three major explanatory hypotheses have been advanced. The first, the "sociogenic hypothesis," asserts that there are intrapersonal, familial, and extrafamilial concomitants of lowerclass status which favor, or at least fail to inhibit, the development of psychopathology. (4, p. 318)

It was precisely because we did not match for social class in the biological parents that we were able to test Dr. Benjamin's hypothesis, along with other hypotheses, that the net effect of the many variables encompassed under social class exerts a significant effect on the development of schizophrenia. After the 33 schizophrenic index probands had been identified, their control adoptees (controls 1) were also selected, matched for age, sex, length of time spent with a biological parent, and socioeconomic status (SES) of the adoptive father. SES was controlled in the rearing family to minimize class-dependent rearing variables, but remained a dependent variable in the biological family. Later, a second and larger group of control adoptees (controls 2) was selected

> by randomly choosing from the adoptee pool two subjects (with no known psychiatric diagnosis) for each index case, matching only for sex and date of adoption. This second group consisted of 66 individuals whose average age approximated that of the adoptees but whose adoptive families' SES were *not* matched with those of the index group. Finally, from the information available, we tabulated the SES of the adoptive and biological fathers of both groups. (4, p. 320)

Dr. Benjamin's hypothesis predicts that the SES of index biological parents will differ from that of the biological parents of the nonschizophrenic controls. Hypotheses of class-dependent environmental variables predict that the SES of index adoptive families will differ from that of the unmatched control adoptive families.

> The means and standard deviation of the three groups are [presented]. [The SES of the biological fathers of index, control 1, and control 2 adoptees were 2.1, 2.3, 2.2, respectively; the SES of the respective adoptive fathers were 2.9, 2.6, 2.7.] There is no significant difference between the mean SES of the biological fathers of the index group and the biological fathers of the two control groups, nor between SES of the adoptive fathers of the index group and the second control group. (4, p. 320)

In the first control group, the SES of the adoptive parents was expected to be the same as that of the index cases, since, as mentioned, the index and control groups were matched on this variable. Lest it be argued that the enumeration and statistics were too insensitive to detect an appreciable difference, a significant difference ($p<0.05$) did occur between the mean SES of adoptive and biological fathers (2.7 versus 2.2).

Those results do not pertain to all environmental influences that may operate in the development of schizophrenia. In fact, there is no doubt in our minds that important environmental determinants exist and should be elucidated by well-designed and rigorous research. These findings merely fail to support simplistic notions of "class" and "societal" determination of schizophrenia. We have not claimed that these results pertain to the mode of genetic transmission; we have not generated "definitive models of human function on the basis of simple statistical contrasts," nor have we pretended to evaluate heritability. Dr. Benjamin's final caveat is not particularly appropriate or relevant. More pertinent would have been the statement of Matthysse and Kidd (5) that "heritability of schizophrenia is not a meaningful concept or statistic, even though the disease has a clear genetic component."

CONCLUSIONS

The results of all of our studies have permitted us to conclude only that genetic factors operate significantly in the schizophrenic syndrome, a conclusion that should disturb only those who assume, without acceptable evidence, that schizophrenia is not a mental illness and is entirely psychosocial in origin. In this connection, a thoughtful and balanced statement by two social scientists, S.C. Plog and R.B. Edgerton (6), seems especially appropriate.

> We continue to believe, for example, that social systems do indeed have the power to program man to suffer all manner of disorders, including what we call neuroses. But, for more serious disorders, such as the psychoses, particularly that chimera called schizophrenia, we urge a second look. We would caution the sciences of man as a social and psychological being not to forget that man is also an animal, and that man's immense plasticity and sensitivity to his social and cultural surroundings should not becloud the fact that he is also a host for micro-organisms, the victim of sundry toxins, and that his primate heritage includes heritable disorders of many sorts. . . . The biogenesis of schizophrenia must be taken seriously; and not only by biochemists and geneticists, but by social scientists as well. Only then will our perspective on mental illness be complete. (6, p. 595)

Prompt Publication Policy

The *Journal* would like to remind authors who are particularly interested in early publication (whether to establish priority of an idea, reveal innovative results of new research, or for other pressing reasons) of its prompt publication policy. Under this policy, short (maximum of six double-spaced pages) manuscripts will be considered for publication in the Brief Communications section of the first available issue. These manuscripts must still undergo expert scrutiny before being accepted, and two months must be allowed for the printing process. However, the time required for publication of these short articles can be lessened considerably.

Authors who would like to have their manuscripts considered under this policy should indicate this desire, as well as the reasons for it, when they submit their manuscripts.

The Legal Implications of Sexual Activity Between Psychiatrist and Patient

BY ALAN A. STONE, M.D.

The author examines the legal and professional sanctions against sex between therapist and patient. The relevant literature of criminal law suggests that charges of rape or related sexual offenses against psychotherapists who exploit their patients are a remote possibility. Although sexual activity between therapist and patient may form the basis of a malpractice claim, the existing case law is complicated, and the legal distinctions are not always consistent with good psychiatric practice. Professional associations lack the legal expertise and indemnification to act in these situations, but medical boards in some states have the power to revoke licenses. In the end, patients must depend on the decent moral character of their therapists.

LAST YEAR at the APA meeting in Anaheim, Calif., Dr. William Masters suggested that any therapist who exploits the power and position of his or her professional status to have sexual intercourse with a patient should be charged with rape. He and Virginia Johnson stated,

> We feel that when sexual seduction of patients can be firmly established by due legal process, regardless of whether the seduction was initiated by the patient or the therapist, the therapist should initially be sued for rape rather than for malpractice, i.e., the legal process should be criminal rather than civil. Few psychotherapists would be willing to appear in court on behalf of a colleague and testify that the sexually dysfunctional patient's facility for decision making could be considered normally objective when he or she accepts sexual submission after developing extreme emotional dependence on the therapist (1).

In this paper I will examine the gap between Masters and Johnson's moral indignation and the existing sanctions in law. There are three specific limitations in the scope of this paper. First, I shall for convenience assume that the problem is one of male therapists being involved with female patients, although the legal ramifications are by no means confined to this assumption; indeed, one of the most well-known criminal cases involved homosexual activities between a male physician and his male adolescent patients (2). Second, I have omitted any discussion of the legal problems of using sexual surrogates other than the psychotherapist in sexual treatment; that would require another paper. Third, I have elected as a matter of personal judgment not to use the names of psychotherapists or patients despite the fact that the records are in most instances in the public domain.[1]

There are three possible legal sanctions against sex between therapist and patient. First there are the various statutes of the criminal law, including rape and rape by fraud or coercion. The latter at least theoretically might be applicable to the situations Masters and Johnson had in mind. Second, there are tort actions, including malpractice, in the civil courts. Third, there is revocation of license to practice by the medical board of licensure. Beyond these legal approaches there are the ethical sanctions of professional associations, societies, and institutions that might potentially have teeth by limiting career opportunities, patient referrals, and staff privileges at various institutional facilities.

CRIMINAL LAW

My review of the legal literature suggests that the criminal courts have been extremely reluctant to adopt Masters and Johnson's suggestion. Rape charges apparently are rarely brought, and, when they are, rarely do they stick. The few reported cases involved some element of physical coercion or force rather than the kind of psychological coercion Masters and Johnson referred to. In fact, in cases in which psychiatrists have been convicted of rape or sexual assault, their behavior has been egregious by almost any moral or legal standard.

Thus an East Coast psychiatrist who gave his patients ECT and/or injections of hypnotic drugs and then had intercourse with them was convicted and served time in prison.[2] Similarly, a West Coast psychiatrist who had intercourse with a 16-year-old girl who

Presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

Dr. Stone is Professor of Law and Psychiatry, Faculty of Law and Faculty of Medicine, Harvard University, Cambridge, Mass. Address reprint requests to him at Langdell Hall, Harvard Law School, Cambridge, Mass. 02138.

[1]The names of the principals of the cases cited have been omitted to protect both patients and physicians from unnecessary public attention.

[2]Cite omitted.

was referred for therapy for promiscuity was prosecuted for and convicted of statutory rape (3).

In contrast to these cases, when a legally competent patient is told that sexual intercourse is to be administered as therapy and the patient consents, the prevailing judicial opinions are that there is no rape because there has been neither force nor fraud (4). However, a few states have passed statutes that specifically encompass Masters and Johnson's moral judgment. The clearest example is Michigan, which has adopted the following statutory language defining coercion in rape: "When the actor engages in the medical treatment or examination of the victim in a manner or for purposes which are medically recognized as unethical or unacceptable" (5). Under this statute sex as therapy might be construed as rape. The implications of this statute are quite novel in that the definition of rape is placed in the hands of the expert witnesses.

Ohio has adopted even broader statutory language, which would inculpate psychotherapists for the lesser offense of sexual battery. The Ohio statute reads as follows: "The offender knowingly coerces the other person to submit by any means that would prevent resistance by a person of ordinary resolution" (6).

Although the criminal law has been invoked almost not at all when a psychotherapist exploits the transference for sexual gratification but does not claim that the sexual activity is treatment, this Ohio statute might be applicable if prosecutors and juries believed that transference creates a coercive relationship.

Summing up, unless new criminal statutes are enacted, criminal charges of rape or related sexual offenses against psychotherapists who exploit their patients are a remote possibility at best.

CIVIL LAW

Let me then turn to the civil area, which involves suits for damages and particularly malpractice. Although it may be an unimportant professional distinction, it is important in these legal cases whether the sexual activity is designated as therapy or not. If a therapist induces a patient to engage in sexual activity on the basis that it is treatment, it will more readily be considered under the rubric of malpractice. If the therapist has an affair with a patient separate from the treatment, no legal cause of action may be available. This legal distinction becomes apparent when suits are brought by husbands whose wives have been seduced by their therapists. In this context the courts seem unwilling to allow the husband's claim of malpractice; indeed, most suits of this sort have failed (7).

However, this legal distinction is somewhat muddied because there are cases in which judges have held that misuse of the transference is a basis for psychiatric malpractice. One southern psychotherapist who told his patient that he was going to divorce his wife and wanted to marry her was said by the court to have engaged in "conduct below acceptable psychiatric and medical standards" (8). The husband was allowed to recover the cost of his wife's hospitalization and treatment. All of the experts in this case agreed that the psychiatrist had acted out his countertransference and that his profession of love was inappropriate.

Presumably, all of the experts would a fortiori agree with the testimony given in a recent case by Dr. Willard Gaylin that "there are absolutely no circumstances which permit a psychiatrist to engage in sex with his patient" (9). All such instances constitute misuse of the transference.

Unfortunately, there are more legal complications to a civil suit of this sort than one might imagine. Many states have passed so-called heart balm statutes that bar civil liability for sexual activity, e.g., seduction, alienation of affections, or criminal conversation. It is the heart balm act that prevents husbands from collecting. In a recent case an East Coast psychotherapist claimed that the heart balm act meant there could be no basis for a malpractice suit by the patient. However, the court held to the contrary that the relationship of a psychotherapist to a patient was a "fiduciary relationship" analogous to that between a guardian and his ward. Further, the court stated that "there is a public policy to protect a patient from the deliberate and malicious abuse of power and breach of trust by a psychiatrist when that patient entrusts to him her body and mind" (9).

The judicial decision that analogized the therapist-patient relationship to the guardian-ward relationship not only undercuts the heart balm act but also does away with the difficult problem of consent.

The facts alleged in this case were that a patient with homosexual predispositions and heterosexual anxiety was induced to have repeated sex with her psychiatrist as a form of therapy. There is in this case, as in all sexual situations that take place in private, the problem of corroborating evidence for the patient's testimony. Ordinarily in such cases testimony as to similar conduct by the psychiatrist could be excluded, but the psychiatrist in this case claimed to be impotent. Therefore, the patient was able to offer the testimony of three other women patients, two of whom reported similar sexual experiences with the psychiatrist and one of whom described blatant and inappropriate sexual behavior and attempted seduction by him. Some of this testimony was stricken from the record as not relevant to the time period during which the psychiatrist claimed impotence. The psychiatrist claimed that the two patients whose testimony was admissible were both suffering from erotomania. The jury, after a lengthy trial, awarded the patient $250,000 compensatory damages and $100,000 punitive damages. However, these huge awards did not remain in effect.

The reasons for the revocation of the amount of damages are quite complex; I will summarize and highlight what I take to be important. First, the therapist's malpractice insurer refused to defend him, leaving the therapist to support three years of litigation on his own. However, after the damage judgment was

awarded, the patient sued the insurance company for part of the damages and settled for $50,000. The therapist pursued his own legal appeals, and in a subsequent decision a higher court dismissed the punitive damages of $100,000 and reduced the compensation award to no more than $25,000. At most, therefore, the patient will receive $75,000, less legal fees.

Furthermore, despite the important holdings in this case, the decision does not clarify the malpractice implications of sex between therapist and patient because there were two lines of defense that this therapist did not assert: 1) that the patient had freely consented to an affair and had known it was not therapy; 2) that the therapist believed sex between the doctor and patient was therapeutic, the patient had been told in advance that sexual activity would be part of the therapy—that is, she had been given full disclosure before the transference developed. Instead, the therapist insisted that the patient had a psychotic transference.

Both of these defenses, although unacceptable to American psychiatry, may still be appropriate defenses in a court of law. Nonetheless, insurers have responded as if sex between therapist and patient is a clear instance of malpractice. The APA insurers have been quick to settle claims. The result is that malpractice rates for all of us will escalate while the offending therapists are protected from the adversities concomitant to a trial.

The American Psychological Association has pursued an alternate avenue: they have obtained insurance that excludes liability for sexual activity. Whether the adverse effects of sex between therapist and patient should be compensable by an insurance policy is, I think, a debatable question.

The problem of estimating the damages suffered in these malpractice suits was reflected in the appellate decision in the case I have been discussing (9). The court reduced the $350,000 award to $25,000. There was one dissenting judge who was prepared to argue that there was no malpractice and no damages. He argued that the civil courts were not the place for dealing with the problems of sex therapy or sex between doctor and patient. As he put it, "Although the plaintiff was suffering from a number of emotional problems, her competency was never placed in issue." Thus he rejected the fiduciary theory, insisting that the patient was legally competent to consent to have intercourse. He went on,

> Is it not fair to infer therefore that she was capable of giving a knowing and meaningful consent? For almost one and a half years while this "meaningful relationship" continued the plaintiff was not heard to complain. Upon the defendant terminating the relationship this law suit evolves.

Although the judge made it clear that he believed the jury finding that the psychiatrist had had intercourse with his patient and that the psychiatrist "obviously did not help his cause by denying what the jury found to be the fact. . . . Nevertheless, however ill-advised or ill-conceived was the choice of his defense, in my view this did not constitute malpractice." He also stated,

> I neither condone the defendant's reprehensible conduct, nor maintain that it was not violative of his professional ethics and Hippocratic oath. . . . For violation of his Hippocratic oath, if there be any, let him suffer the sanctions of the medical ethics board or other appropriate medical authority.

In this disposition of turning the case over to the medical licensing board and the profession for appropriate action, the dissent was in fact joined by the majority, who stated,

> Sex under cloak of treatment is an acceptable and established ground for disciplinary measures taken against physicians either by licensing authorities or professional organizations.

Interestingly enough, the court did not foreclose the matter of whether the psychiatrist should be deprived of his license or sanctioned by his professional organization:

> Whether defendant acted in such manner as to seriously affect his performance as a practitioner in the psychiatric field should be left to these more competent fora. The only thing that the record herein supports is that his prescribed treatment was in negligent disregard of the consequences. For that and that alone he must be held liable.

PROFESSIONAL BOARDS AND ASSOCIATIONS

As one looks at the capability of licensing boards and professional associations, which were considered "the more competent fora" by that court, according to my research there is an almost total lack of capacity to act. The professional associations have no subpoena power and no expertise in criminal or other evidentiary investigation. They have neither formulated necessary procedures nor employed sufficient legal staff to protect the due process rights of a doctor charged with some such act or themselves if the charged doctor sues them. Indeed, it often happens that, because his or her whole career is at stake, a doctor charged with any ethical complaint hires a lawyer who immediately threatens to sue the society, the association, and its ethics committee, all of whom have no indemnification. That characterization, I must confess, is up to this point an accurate description of APA. However, we are not alone. Lawyers expert in private association law tell me that none of the associations has the proper machinery and that many of them behave as we do, by postponing any and all action until all legal appeals are exhausted in the criminal and/or civil area.

Finally, then, we turn to the licensing boards in hopes that something can be done there. The fact that a number of cases exist in which licensing boards have

actually revoked licensure for sexual activity of doctors with patients suggests that some power resides in these boards and is being used.[3] However, the licensing boards in each of the states are organized quite differently. Some have a close relationship to the medical society, others do not, and some are impotent bureaucracies reluctant to do anything. Therefore, one cannot expect real consistency across the different jurisdictions. Each jurisdiction has enabling statutes that limit the scope of authority.

In one western state, for instance, a doctor guilty of the grossest sexual impropriety could not have his license revoked because the only ground was "grossly negligent or ignorant malpractice"; his board found that he was guilty of "grossly negligent or immoral malpractice" (13).

COMMENT

I have briefly described four possible avenues for punishing, disciplining, or deterring sexual activity between therapist and patient. None of these avenues seems to provide an effective system of control. In the end, in this as in most other things, patients must depend on the decent moral character of those entrusted to treat them.

[3]There have been at least eight reported appeals from license revocation that were grounded on sexual impropriety by a physician. Several were by psychiatrists (10–12).

The Alcoholic Physician: A Survey

BY LECLAIR BISSELL, M.D., AND ROBERT W. JONES, M.A.

The authors conducted interviews with 98 recovered alcoholic physicians, all of whom had been entirely abstinent for a minimum of one calendar year. Psychiatry was the only specialty clearly overrepresented. A disproportionate number of subjects reported high standing in their medical school classes. Nearly half of the sample had experienced difficulty with drugs other than alcohol. While legal sanctions and admission to health care and correctional institutions were common among this group, relatively little formal response of a disciplinary nature from colleagues or medical organizations was reported.

ALTHOUGH THE PROBLEM of drug dependence in our society is receiving increased public and professional attention, information about the alcoholic physician is still relatively scarce. Seventy percent of adult Americans do drink, and of these an estimated 6% to 10% develop alcoholism (1). Assuming that physicians do not differ from their countrymen in drinking practices, then about 226,800 of our 324,000 physicians (2) are drinkers and between 13,600 and 22,600 are or will become alcoholics. The actual number is likely to fall toward the upper end of this range because of the large number of men in the physician population and because of the apparent relationship between alcoholism and higher educational attainment (3). More than 4 times as many men as women are alcoholics (3). The proportion of drinkers among college graduates is markedly higher than that among other educational levels, and generally, the greater the proportion of drinkers, the higher the rate of alcoholism. In addition, Glatt (4) reported an above average standard mortality rate from cirrhosis of the liver among English physicians, and many studies of physicians undergoing psychiatric treatment have reported that alcoholism is a common finding (5–12).

Dr. Bissell is Chief, Smithers Alcoholism Treatment and Training Center, Roosevelt Hospital, 428 West 59th St., New York, N.Y. 10019. Mr. Jones is Adjunct Professor of Sociology, Rutgers Center of Alcohol Studies, New Brunswick, N.J.

This work was supported in part by a grant from the Richard Ettinger Foundation, New York, N.Y.

The authors wish to express their appreciation to Barry Leach, Barbara Goodman, Ph.D., Jean Meyer, Judy Stires, and Elizabeth Kahn, all of whom variously worked on questionnaire design, interviewing, analysis, and typing for this study.

That alcoholism frequently precedes or underlies addiction to other drugs has been mentioned repeatedly. Vincent (13) stated that half of all alcoholic physicians eventually develop drug addiction. Modlin and Montes (14) reported that 25 physician addicts at Menninger Memorial Hospital, Topeka, Kan., all used varying amounts of alcohol, analgesics, sedatives, or ataractics in combination with narcotics. In a 1966 study of 68 physician addicts at the U.S. Public Health Service Hospital in Lexington, Ky., alcoholism, chronic fatigue, and physical disease were the principal reasons given for the beginning of self-medication (15). Also frequently reported is the high incidence of alcoholism in association with physician suicides (16). Blachly and associates (17) studied 80 physicians who killed themselves during the period 1965–1967 and found that 39% were described as alcoholic or heavy drinkers and 19% were drinking at the time of their death.

Most of the available information about the alcoholic physician is drawn from observations of hospitalized patients or those under psychiatric treatment. We found only one prospective study in the literature, that of Vaillant and associates (18), who reported that in a group of 45 physicians "selected for psychologic health," self-medication with drugs or alcohol was the cause of one-third of the total time that this group spent in the hospital. Further, 36% of the physicians, compared with 22% of the control group, were categorized as being in the "high drug use" groups, which included "heavy drinking or 'trouble with control of alcohol' " (19).

The study from which this paper is drawn examined alcoholic physicians who had successfully stopped drinking, who were not institutionalized, and, for the most part, were not under psychiatric care at the time of the study. There appear to be no other studies of physicians and alcoholic populations that are not currently in treatment and in which the disease is not active.

METHOD

American and Canadian male physicians who had grown up in the United States or in English-speaking Canadian families were selected for the study. All considered themselves alcoholics, were members of Alcoholics Anonymous (AA), and had been totally abstinent for 1 calendar year or more prior to interview. While we attempted to locate sober alcoholic physi-

cians who are not members of AA, we were unable to find a large enough number to provide comparability.

We located the subjects primarily through the cooperation of International Doctors in AA, a chapter of Alcoholics Anonymous limited to physicians and dentists[1] which holds an annual August weekend meeting in various parts of the United States. Other subjects were found through local AA groups. We also located several men who were practicing in small towns in the Carolinas and Georgia and were known to one another. Each willingly introduced the interviewer by telephone to the next physician down the highway.

In no case did an AA member give a physician's name without first obtaining his permission to do so. It is therefore possible that some of the reports that potential subjects were away on vacation or were ill may represent their refusal to be interviewed. We made no attempt to conduct a random sampling or develop a control group. Since considerations of time and geography made it impractical to visit many western and small communities, most of the interviews were conducted in eastern urban areas, frequently during medical conventions.

A 50-part questionnaire using some items modified from a previous study (20) was administered in a face-to-face interview with each of the subjects. The interviewer recorded all of the information with the exception of a checklist of symptoms of alcoholism, physical sequelae, and social sanctions experienced, which was marked by the subject.

All interviews were conducted during the period 1968–1970 and were solicited by the study team. While only 1 of the physicians approached actually refused to be interviewed, 3 others also refused, in effect, by engaging in delaying tactics and by making it extremely difficult to contact them.

RESULTS

Characteristics of the Study Population

The study resulted in 98 usable questionnaires. Table 1 compares the study population's distribution by field of practice to that of all U.S. physicians.

A striking proportion of the alcoholic physicians identified themselves as psychiatrists at the time of the interview, although in at least 3 cases the current field of practice was not the same as it had been at the time of cessation of drinking. Since the study population was not a random sample, the differences found may be related to sample variation or to differential rates of alcoholism among practitioners in the various fields. However, except for the field of psychiatry, the 2 groups did not appear to be distributed differently by field of practice.

Data on the study group's class standing in medical school also suggest that these physicians are not representative of the total physician population.

[1]Information may be obtained from the Secretary, International Doctors in AA, 1950 Volney Rd., Youngstown, Ohio 44511.

TABLE 1
Comparison of the Field of Practice of All U.S. Physicians and of 98 Alcoholic Physicians at the Time of the Interview, in Percents

Field of Practice	All U.S. Physicians*	Alcoholic Physicians
General practice	22	24.5
Internal medicine	14	13.3
Surgery	10	9.2
Psychiatry	6	17.4
Obstetrics and gynecology	6	9.2
Pediatrics	6	2.0
Radiology	3	2.0
Anesthesiology	3	4.1
Pathology	3	3.1
Ophthalmology	3	0
Orthopedic surgery	3	3.1
Other	21	12.3

*Data are from the American Medical Association (21).

Of the 84 physicians who provided data on this item, 45 (53.6%) reported that they were in the upper third of their class (including 19, or 22.6%, who were in the upper tenth), 34 (40.5%) were in the middle third, and 5 (5.9%) were in the lower third. Fourteen physicians stated that their medical schools did not report these rankings to their graduates; we checked with the schools of 4 of these physicians and found this information to be accurate.

A normal distribution would obviously have produced about one-third in each level. Again, we cannot ascribe the findings to either sample variation or to differences in an alcoholic population. However, the 2 distributions (field of practice and class standing) do suggest that the alcoholic physician may well be different from his nonalcoholic colleagues in characteristics other than his disease.

A total of 91 subjects were working full time as physicians. Five were semiretired due to reasons of health. One had retired completely (he was well into his 70s and had been abstinent for over 20 years), and another had left active practice to become a medical writer.

Twenty-one were holding formal teaching appointments in medical schools, although the colleagues and students of only a few knew that they were recovered alcoholics. They therefore did not share their experience with their peers. Several indicated that they would like to do so but were afraid of the stigma that might follow honest disclosure.

While only 1 consecutive year of total abstinence was required for inclusion in this study, the mean period of total abstinence was 7.4 years, with a range of 1 to 29 years.

Addiction to Other Drugs

As with groups in previous studies, our study sample also reported a high incidence of addiction to drugs other than alcohol. A total of 56 (57.1%) had

been addicted only to alcohol, 24 (24.5%) to alcohol and "soft" drugs, 4 (4.1%) to alcohol and narcotics, and 14 (14.3%) to all three.

We did not attempt to define "addiction" for the individual physician. If he considered himself to have been addicted to a given drug, his word was accepted. If, on the other hand, he expressed uncertainty as to whether he had merely used a drug or had actually been addicted to it, he was regarded as not addicted.

The category of soft drugs included sedative-hypnotics, tranquilizers, amphetamines, and volatile anesthetics. Codeine, whether used alone or with terpin hydrate, was included with the narcotics.

Table 2 presents data on the drugs other than alcohol to which the physician reported addiction. It should be borne in mind that since most of these physicians stopped using other drugs at the time they stopped using alcohol and that since many had been sober for years at the time of interview, this choice of drug reflects a pattern of use probably not typical of today's active drug abuser. For example, few of our subjects mentioned diazepam, which is probably the most frequently abused drug in our present patient population, and none mentioned methaqualone hydrochloride or pentazocine hydrochloride, although both are now frequently used by self-medicating physicians.

TABLE 2
Drugs of Addiction Other Than Alcohol Among 98 Alcoholic Physicians

Drug	Number*	Percent
Narcotics	18	18.4
Barbiturates	29	29.6
Amphetamines	17	17.3
Glutethimide	11	11.2
Meprobamate	8	8.2
Chlordiazepoxide	8	8.2
Chloral hydrate	7	7.1
Ethchlorvynol	3	3.1
Diazepam	3	3.1
Bromide	1	1.0
Gas and volatile anesthetics	1	1.0

*A number of subjects reported addiction to more than one drug.

Federal hospital	7
Mission, halfway house, and municipal shelter	6

*Includes Veterans Administration hospitals.

Treatment Experience

All but 22 of the subjects (22.4%) sought professional help for alcoholism or what they later recognized as alcoholism, and many sought help from more than one type of professional. They consulted psychiatrists more frequently than nonpsychiatric physicians (52 subjects, or 53.1%, versus 40, or 40.8%); in addition, almost one-third of the group (32, or 32.7%) approached the clergy.

Contrary to the popular impression that alcoholics do not remain in treatment, of those subjects who sought psychiatric help 37 (71.2%) stayed in treatment for 2 or more years and 15 (28.8%) for 8 or more years.

While many described their overall treatment experiences as helpful, they frequently complained that a professional helper had refused to identify or deal with the problem of alcoholism per se and had chosen to regard it as a symptom of some other underlying condition. Thirty-four men reported that the question of alcoholism had specifically been discussed between patient and therapist, only to have the therapist deny the fact of alcoholism. Since it is virtually impossible to arrive at a reasonable treatment plan for a disease whose existence is not acknowledged, this behavior had frequently resulted in dangerous delays in obtaining appropriate treatment.

Most of the study sample reported multiple treatment experiences as inpatients, outpatients, or both. A total of 77 (78.6%) were institutionalized 1 or more times, while 21 (21.4%) were not. Table 3 presents information on all admissions to institutions for alcoholism or alcohol-related illness regardless of the diagnosis officially recorded at the time. The total time these physicians spent in institutions during their 627 admissions was just under 39 years. (If one assumes that there are in fact over 5 million alcoholics in the United States today, and if the use of health care facilities reported by these physicians is accurate and typical of other alcoholics, the drain on the health care dollar is even more staggering than previously estimated.)

Medical Sequelae

In addition to the difficulties resulting from simple physical addiction to alcohol, the physicians also reported experiencing many of the common somatic complications of alcoholism (see table 4). Often these conditions required hospitalization. Several of the subjects stated that they received excellent physical care during inpatient treatment of these conditions but that they and their doctors tacitly agreed not to discuss the matter of alcoholism.

An additional physical hazard was presented by the subjects' tendency to use other drugs in an attempt to deal with the insomnia, agitation, and depression caused by excessive drinking. (The alcoholic physician frequently confused cause and effect and believed that his problems with sleep and his nervousness caused him to drink, rather than the reverse.) As the use of other sedatives increased, frequently in a setting

TABLE 4
Medical Complications of Alcoholism Reported by 98 Physicians

Complication	Number*	Percent
Gastritis	44	44.9
Peripheral neuropathy	19	19.4

Fatty liver	14	14.3
Gastrointestinal bleeding	14	14.3
Peptic ulcer	10	10.2
Pancreatitis	5	5.1
Cirrhosis of the liver	4	4.1
Esophageal varices	1	1.0

*A number of subjects reported more than one type of complication.

TABLE 5
Professional Sanctions Experienced by 98 Alcoholic Physicians

Sanction	Number*	Percent
Admonished by colleague	58	59.2
Warned by medical society or licensing board	20	20.4
Lost hospital privileges	20	20.4
Lost medical license	8	8.2
Lost narcotic license only	1	1.0
Never sanctioned	33	33.7

*A number of subjects experienced more than one sanction.

of increasing alcohol use, the physician often became confused as to how much he was taking. Twenty-three men reported serious sedative overdoses, most of which were not felt to have been suicide attempts.

The physicians were asked specifically about any overt suicide attempts. No effort was made to distinguish between serious attempts and gestures. If a subject reported a self-destructive episode but was unclear as to whether he was consciously attempting suicide, we did not list it as an attempt. Fifteen subjects (15.3%) reported that they had made overt suicide attempts. Ten subjects (10.2%) had made a single attempt, 1 (1%) had made 2 attempts, and 2 (2%) each had made 3 and 6 attempts. Because of the criteria we used for listing a self-destructive episode as a suicide attempt, these data probably represent underreporting rather than the opposite.

Social Sequelae

Since it has been our experience that patients who are obviously seriously alcoholic often defend against diagnosis on the grounds that they are still able to work, we were particularly interested in the effect of alcoholism on the physicians' work performance.

We found that over half of the sample (53, or 54.1%) did not experience any obvious change in job status as a result of drinking. (This does not, of course, take into consideration the quality of work or volume of practice.) Among the 45 who did report work difficulties, 20 suffered periods of unemployment and 5 were forced to work outside the medical field altogether, 1 as a porter, another as a dishwasher, and yet another as a copier of blueprints. Of those who remained in medicine but reported a decline in work status, several reported that their careers were dramatically affected. For example, a chief of medicine at a major medical school took a series of locum tenens positions for general practitioners. A famous pathologist worked as little more than a laboratory technician for another physician. A neurosurgeon deprived of hospital privileges supported himself by doing routine physical examinations.

Many of the physicians experienced difficulty with the law, and many others stated that while they had never been arrested, they felt that they should have been but the police were often lenient when an erratic driver or boisterous individual was identified as a doctor. A total of 48 subjects (49%) had been arrested, 37 (37.8%) had been jailed, and 19 (19.4%) had lost their driver's license. Our sample of physicians accumulated a total of 219 arrests and 170 jailings.

Response of the Profession

Table 5 lists the professional sanctions experienced by the alcoholic physicians. Included under "admonitions" was any statement (informal or otherwise) made by a colleague or superior to the effect that drinking was perceived as a problem. It is therefore particularly telling that in one-third of these cases, nothing whatsoever had been said.

DISCUSSION

These 98 alcoholic physicians were probably clearly visible to the general public and to their colleagues. The public response to their behavior, as represented by arrests, jailings, and loss of driver's license, occurred more often and with a larger number of formal indications of disapprobation than did the professional response, as represented by warnings from medical societies and licensing boards, loss of hospital privileges, and actual loss of license.

That the public was more aggressive in its response than was the medical profession raises issues about the self-regulation of colleagues by a professional group. Arrests and jailings are not actions lightly undertaken by police in response to a transient action by a physician. Police are frequently reluctant to arrest the more prominent and respected citizens of a community. Several of the subjects stated that while they had not been arrested, they felt they should have been.

It is noteworthy that many of the physicians stated that their alcoholism had never resulted in injury to their patients. Although this feeling is often shared by the colleagues of alcoholic physicians, it is a view that is difficult to accept. Since alcoholism interferes in so many ways and with such a multiplicity of functions, there can be little doubt that the patients of an alcoholic physician receive a lesser level of care than that physician is able to deliver when he is sober. The question

of injury to the patient is much more subtle, although the probability that such injury occurs is much more likely than the alcoholic physician is able to recognize.

The medical field has recently (22, 23) been willing to acknowledge that its members are not immune to problems of alcoholism, addiction, and mental illness and to move toward the development of legislative and administrative means to protect them from doing harm or being harmed. One hopes that other professional groups will follow this lead.

REM Sleep and Adaptation of Psychiatric Patients: An Application of Sleep Studies

BY RAMON GREENBERG, M.D., AND CHESTER A. PEARLMAN, JR., M.D.

The authors used sleep laboratory data to predict responses to psychiatric treatment. The predictions were based on the assumptions that REM latency reflects the need for dreaming and therefore the need for adaptation and that REM time reflects the capacity for the adaptive work associated with REM sleep. Dream recall and dream content were considered indicators of psychological mindedness and the patient's current conflicts. With this material, statistically significant predictions of such outcomes as good response to psychotherapy, elopement, or need for medication were made. The results of this study support the hypothesis that REM sleep is involved in adaptation.

SLEEP STUDIES of various clinical disorders have generally failed to reveal patterns specific enough for diagnostic use. The most notable exception is the study of narcolepsy (1). The present investigation differs from naturalistic studies in that our approach is based on the formulation that one function of REM sleep is the integration of new, emotionally meaningful experiences with earlier, similar experiences in the service of psychological adaptation.

Two previous studies (2, 3) showed that variations in REM latency and REM time could be predicted from the mental state of a patient before and after sleep. (REM latency is the number of minutes of sleep from sleep onset to the first occurrence of REM sleep; REM time is the number of minutes of REM sleep during the night, or the percent of sleep that is REM.) Our assessment of mental state involved scoring material for a variable we called "defensive strain." The measure of defensive strain included assessment of ego-dystonic affect, efficiency of defensive operations, and prominence of threatening self-other fantasy constellations. We predicted and found that high defensive strain before sleep was associated with shorter REM latencies and that changes in defensive strain from evening to morning were correlated with REM time (fall in strain was correlated with higher REM time and rise in strain with lower REM time). These predictions were based on the idea that high defensive strain reflects a need for the adaptive work hypothetically associated with REM sleep.

In the present study we tested the following corollary assumptions of our previous studies: 1) REM latency reflects the degree of defensive strain (need for adaptive work), and 2) REM time reflects a patient's capacity to integrate emotionally arousing experiences. In other words, the pressure to dream (REM latency) reflects the need to integrate experiences, and the amount of REM reflects the ability to accomplish the task. In addition to the sleep physiological data, we collected dream reports at the end of REM periods. Although the normal subject has about 80% dream recall after REM awakenings, we had found considerable variability among patients. We felt that dream recall reflected the patient's attitude toward his inner life. Thus, presence or absence of recall could be an index of psychological mindedness. Finally, we also felt that the nature of the dream content might give some indication of the issues with which the patient was struggling and of his methods of coping with them. Therefore, we expected that REM measurements and dream reporting would be useful in predicting some aspects of a patient's response to hospitalization. For example, would he be accessible to psychotherapy, would he react negatively to the hospital and elope, or would he need medication before being able to deal with his problem?

METHOD

Forty-four male inpatients were selected for study. We studied any patient admitted to the psychiatry service of the Boston Veterans Administration Hospital who would agree to spend two nights in the sleep laboratory during the first two weeks of admission. Our technician first asked the physician of each new patient and the nursing personnel for permission to discuss the project with the patient. The technician then explained the study to the patient and obtained his agreement to participate. We never saw the patients or heard anything about their histories. Each patient spent two nights in the laboratory, usually within three days of each other. The first night of sleep was recorded without any awakenings. If a patient happened to awaken and mention a dream, his report was recorded.

Dr. Greenberg is Director, Psychiatry Research, and Dr. Pearlman is Staff Psychiatrist, Boston Veterans Administration Hospital, 150 S. Huntington Ave., Boston, Mass. 02130.

The authors wish to thank their technician, Mr. Michael Becker, for his sensitive and effective manner of dealing with the patients.

On the second night, awakenings were made at the end of each REM period,[1] the presence or absence of dream recall was noted, and dream reports were obtained if the patient was able to present them. The only questions asked by the technicians were: Were you dreaming? Was anything going through your mind? and Could you tell more about it?

Each record was scored twice for REM and non-REM (NREM) sleep. The results were tabulated for REM latency, REM time, REM percentage, and total sleep. The tape recordings of the patients' accounts of their dreams were transcribed. These were the only data provided to us; we made our predictions independently after studying these data. The following guidelines were developed for the predictions:

REM latency. 1) Short latency (less than 40 minutes) would suggest high defensive strain and therefore a subjective feeling of distress in the patient and a need for some resolution, e.g., by psychotherapy, medication, or leaving the hospital. (Short REM latency might also be due to withdrawal from a REM-suppressing drug, e.g., alcohol; the scorers would not know this information.) 2) A long REM latency (more than 100 minutes) would suggest low intensity of factors involved in defensive strain. Therefore, whatever the patient might be feeling was not ego-dystonic, and motivation for therapeutic efforts would be minimal.

REM time. 1) Low REM time (less than 40 minutes or 15%) would suggest that the patient lacked the capacity or need to integrate current experiences with the earlier conflicts these experiences stirred up, either because he was overwhelmed and could not sleep well or because he lacked the ego structures necessary for this task. In either case, he would probably not be able to make use of psychotherapy, although treatment with tranquilizing drugs might change the picture. 2) Average REM time (40–100 minutes or 15%–30%) would suggest that the patient was able to integrate emotionally meaningful experiences and to reconstitute defenses. 3) Unusually high REM time (more than 100 minutes or 30%) might represent drug withdrawal or remission following an acute psychotic episode.

Dream material. 1) Poor recall from REM awakenings would suggest a reluctance to recognize or think about psychologically meaningful material. 2) Clinical judgment was used for assessment of the dream material. For example, dreams incorporating the hospital experience might suggest the capacity to become involved with the hospital and to attempt to deal with the experience. The patient's interactions in the dream might give some clues about issues with which he was currently concerned, such as running away from the hospital or talking with the doctor.

With these guidelines, the following predictions were made:

1. Patient will be accessible to insight-oriented psychotherapy. He will become involved in exploration of his problems and show behavioral alterations resulting from the therapy relationship. (Low to average REM latency reflects subjective distress and need for change; average to high REM time reflects ability to integrate experiences; and good dream recall with evidence of current conflicts reflects capacity to introspect.)
2. Patient will reject attempts to help. He will leave the hospital by signing out or eloping, claiming that the hospital upsets him or that he does not need help. (Low REM latency reflects subjective distress and need to change; low REM time reflects poor ability to integrate experiences; and poor dream recall or dream content suggests flight.)
3. Patient will need medication before he can make use of help. (Sleep so fragmented that REM measurements are meaningless, or low REM latency and low REM time, but better dream recall and content, are more suggestive of accessibility to treatment than in prediction 2.)
4. Patient will reconstitute rapidly and establish his characteristic defensive patterns. (Average to high REM latency reflects little inner distress or need to change; average to high REM time reflects ability to integrate precipitating stress; and, although dream recall is low, recalled material suggests institution of defenses.)
5. Patient will stay in the hospital and develop a dependent relationship or return to a similar situation at home. (Average to high REM latency reflects not much distress; average to low REM time reflects not much capacity for integration and a need for external support; and dreams suggest strong, ego-syntonic dependency.)

The patients' charts were not consulted until after we had read their sleep records and made our predictions. We waited for at least two months and as long as six months after the patients' admissions in order to have a clear picture of the actual course of their hospitalizations. In most cases the outcome was unequivocal. When there was any question, such as the relative role of drugs versus psychotherapy, we arrived at consensus by careful discussion of the material in the chart.

RESULTS

When the outcomes were examined, all five predicted hospital courses were well represented (range, 5–15). Thus, our chances of predicting any outcome were between 1 in 3 and 1 in 8. Because of differences in sleep measurements between first and second nights or differences between the sleep measurements and the dream material, we sometimes made predictions of two possible outcomes. Our chances of being right in this case became about 2 in 5. We scored our predictions as plus (+) if the prediction precisely coincided with the outcome, plus/minus (±) if 1 of 2 predictions

[1]The end of a REM period was defined as the first appearance of a sleep spindle without evidence of continued eye movements or three minutes of waking following a REM period. Awakenings were within three minutes of the end of a REM period.

TABLE 1
Outcomes for 44 Inpatients by Predictions Made by 2 Scorers

Outcome	Number Predicted To Have Outcome by Scorer 1*					Number Predicted To Have Outcome by Scorer 2*				
	1	2	3	4	5	1	2	3	4	5
1. Patient is accessible to psychotherapy (N=15)	4	0	0	2	5	10	0	1	1	2
2. Patient rejects attempts to help (N=8)	0	1	0	3	2	2	3	0	1	0
3. Patient needs medication (N=5)	0	1	2	1	1	1	1	2	1	0
4. Patient reconstitutes rapidly (N=11)	1	2	0	5	1	1	0	2	3	1
5. Patient develops dependent relationship in the hospital or returns to one at home (N=5)	1	0	0	0	2	2	0	1	0	2

* For prediction 1, scorer 1 also had 4 plus/minuses; for prediction 2, 2; for prediction 3, none; for prediction 4, 2; and for prediction 5, 2. For prediction 1, scorer 2 also had 1 plus/minus; for prediction 2, 2; for prediction 3, none; for prediction 4, 4; and for prediction 5, none.

TABLE 2
Expected Correct Predictions Versus Actual Correct Predictions for 2 Scorers

Outcome	Predictions of Scorer 1*		Predictions of Scorer 2**	
	Expected	Actual	Expected	Actual
1. Patient is accessible to psychotherapy (N=15)	3.409	6	5.795	11
2. Patient rejects attempts to help (N=8)	1.091	2	1.091	4
3. Patient needs medication (N=5)	.227	2	.682	2
4. Patient reconstitutes rapidly (N=11)	3.250	6	2.500	4
5. Patient develops dependent relationship in the hospital or returns to one at home (N=5)	1.477	3	.568	2
Total	9.454	19	10.636	23

**χ^2=19.028; p<.001.

coincided with the outcome, and minus (−) if the outcome differed from our predictions. With this scoring method, one of us had 14 pluses, 20 minuses, and 10 plus/minuses, and the other had 20, 17, and 7, respectively.

Table 1 shows the distribution of predictions and outcomes for each scorer. Using these results, we prepared table 2 to show the distribution of expected outcomes[2] as compared with predicted outcomes. (For statistical purposes, plus/minus scores were randomly assigned to either minus or plus categories.) This was done for each outcome for each scorer. Chi-square analyses were then computed; these showed that the predictions were significant (see table 2). The reliability of scoring was assessed by comparing the predictions of the two scorers irrespective of the correctness as measured by outcome. On this basis there was no agreement in 12 of 44 predictions, complete agreement in 24 of 44, and 8 in which one or both scorers gave 2 predictions and 1 of them coincided. Thus, predictions for 73% of the patients were either completely or partially in agreement.

We also examined the data to see whether REM latency or REM time by themselves would have any predictive value: we found no significant relationship to any particular outcome. It is of interest, however, that 9 of 15 patients with good dream recall (more than 2 REM awakenings with 2 or more detailed dreams reported) were in outcome 1, accessibility to psychotherapy, but only 6 of 29 patients with poor recall responded to psychotherapy.

The patients who represented exceptions to dream recall as a predictor are also instructive. One patient had poor dream recall, but the one fragment he reported involved his family. His REM latency and REM time were predictive of a good response to psychotherapy, and he made good use of psychotherapy. On the other hand, one patient who recalled three of five dreams had outcome 4, rapid reconstitution. His dream content indicated a great deal of embarrassment about revealing himself. Thus, it appeared that using all of the data increased our ability to predict outcomes.

Some clinical examples of our successful and unsuccessful predictions can illustrate the use and problems of this kind of assessment. One patient had short REM latencies and moderately high REM time (25%). On four REM awakenings, he recalled three dreams whose content indicated his longings. Our prediction was that he should be able to work in psychotherapy. The chart revealed that the initial diagnostic impression was that the patient was a sociopath and a chronic alcoholic. This patient surprised the staff by becoming involved in treatment, requesting disulfiram (Antabuse) and working on problems in his marriage; improvement occurred over a period of months.

Another patient showed short latencies and high REM (157 minutes one night). He had poor recall of dreams, remembering only a fragment that involved taking an airplane to Hawaii. His sleep measurements suggested internal pressure and an attempt to deal with

[2]"Expected" is the statistic calculating what might occur by chance given the uneven numbers of outcomes and predictions.

this by high REM. His dreams suggested repression and flight. One of us relied primarily on the sleep measurements and predicted that the patient would get involved in psychotherapy. The other felt that the paucity and content of the dream material outweighed the high REM time and predicted that the patient would reject attempts to help him. The chart revealed that the patient had had a psychotic break and had been hospitalized for 10 months before coming to our hospital. He was diagnosed as not psychotic and left the hospital having gained no insight after 3 weeks.

Another patient had very long REM latencies and average REM time. He recalled only a fragment on one of two REM awakenings. We predicted that this patient would reconstitute his usual defenses and not get involved in psychotherapy. He improved after an acute schizophrenic episode with the help of chlorpromazine (Thorazine) and was discharged, off medication, in 2 weeks.

DISCUSSION

We have described how sleep data alone enabled us to make fairly accurate predictions about whether a patient would make use of psychotherapy, would reject efforts to help him, or might need medication before he could enter into treatment.

The reliability of our scoring deserves comment. Although our directions for scoring were quite explicit, occasionally we could make entirely different predictions from the same data. One cause of this phenomenon was a discrepancy between dream material and the physiological findings. In one case low REM latency and high REM time suggested accessibility to psychotherapy but the dream material showed evidence of a greal deal of repression. Other causes were differences in REM measurements between first and second nights or borderline values between two predictive categories. Thus, the laboratory results are at times equivocal and lead to differing predictions.

Some additional possible reasons for our inaccurate predictions also deserve mention. Many of these will be obvious to the experienced clinician. For example, although the laboratory results suggested a favorable outcome with psychotherapy, the patient might have had a therapist to whom he could not relate well. Conversely, a patient who appeared inaccessible to therapy might have found just the right person for establishing a therapeutic relationship. Withdrawal from alcohol or drugs (of which the scorers were unaware) might lead to high REM times and an inaccurate prediction of capacity to use psychotherapy. Conversely, even when sleep was not obviously fragmented, psychotropic drugs might have reduced anxiety and thus increased REM time, resulting in greater benefit from psychotherapy than we had predicted.

A study by Gillin and associates (4) illustrates this last situation. They found that acute schizophrenic patients deprived of REM sleep showed no REM rebound until the third recovery night, although REM latency was shorter on these nights for the schizophrenic patients than for a nonpsychotic control group. To us, these findings suggest impaired capacity to respond with increased REM in the acute schizophrenic patients despite increased REM pressure (short latencies). However, schizophrenic patients who were receiving phenothiazines showed more rebound than untreated patients. Phenothiazines might therefore improve the capacity for REM sleep through direct effects on the chemical pathways involved in REM sleep or indirectly by influencing the psychological state of the patient.

In another study, Reich and associates (5) presented correlations of REM latency and REM activity with response to drug treatment in a series of schizophrenic patients. They found REM measurements to be useful in predicting response to phenothiazines and in identifying patients who required antidepressant medication. In both Reich and associates' study and ours, sleep laboratory data were viewed as an aid to predicting patients' responses to treatment. Although clinicians have other methods for making such assessments, we feel that such data, when available, can improve treatment planning.

Of additional importance is the idea that sleep patterns in psychiatric patients should be seen as a reflection of underlying processes rather than as symptoms to be treated in isolation. REM latency, REM time, and dream recall and content can be used as indicators of the psychological state of the patient independent of the clinical diagnosis. Although not readily available, this method may find application for some psychiatric patients and also illustrates how a clinical study may be helpful in testing theories, in this case that REM sleep plays a role in adaptation.

Atypical Facial Pain as a Defense Against Psychosis

BY JOHN F. DELANEY, M.D.

The author describes three women who presented psychotic symptoms 24–48 hours before scheduled neurosurgical procedures for atypical facial pain; all had had extensive dental reconstruction and attempted nerve blocks with no relief. Psychiatric hospitalization and administration of major tranquilizers resulted in control of symptoms and relief of pain. Two patients were followed for a year and have had no return of psychiatric symptoms or facial pain; both have been maintained on medication and have returned to normal activities. The author suggests that the facial pain may have served as a defense against the emergence of psychosis.

THERE HAS BEEN great interest in the possible psychological and organic causes of atypical facial pain since Frazier and Russell (1) first differentiated such patients from the larger group of individuals with characteristic trigeminal neuralgia. Glaser (2) and others believed that psychoneurosis could be the causative factor in atypical facial pain. Wilson (3) pointed out that in some cases the behavioral and personality changes were out of proportion to the symptoms. He noted that many of these people had similar personality types and considered the pain to be an externalization of conflictual material. More recently, Dalessio (4) discussed the role of depression in head and facial pain; several such patients have also been described by Gallemore and Wilson (5). Engel (6) has suggested that atypical facial pain is a conversion symptom.

In this paper, I will not reexamine previous hypotheses regarding atypical facial neuralgia; rather, I will present the idea that this pain may be a defense against psychosis. The three cases I will describe have several factors in common that support this hypothesis.

CASE REPORTS

Case 1. Ms. A, a 44-year-old single woman, had complained of left-sided facial pain for 3 years before her hospitalization. The pain was described as gradual, boring, and dull, eventually migrating to the entire left side of the face and then to the right side. At first, she was able to obtain relief with simple analgesics. When the pain became persistent, she consulted dental surgeons, who removed decayed maxillary teeth bilaterally.

The extractions brought her relief for approximately three months, after which time her original symptoms returned and the pain became severe and unrelenting. A consultation with oral surgeons revealed a possible malocclusion and the patient was given braces. Narcotics were prescribed for pain and barbiturates for sleep. When she experienced no relief, she became angry and belligerent toward her employer and customers as well as her physicians. She began to abuse narcotics and used heavy doses of barbiturates. After X-rays revealed mild temporomandibular arthritis, she underwent bilateral condylectomy, which relieved her pain for approximately 4 months. She continued to use narcotics and barbiturates but in smaller doses and was able to function at work.

Several months after the condylectomy, Ms. A again experienced bilateral facial pain, this time of a boring nature with no specific radiations. She was referred to the Pain Clinic at the University of Pittsburgh School of Medicine and received bilateral trigeminal nerve injections. She increased her use of narcotics and barbiturates to the point of severe addiction, missed a great deal of work, and was in danger of being fired. Her physicians felt that she should be admitted to the neurosurgical service for a definitive pain procedure, and a left posterior fossa exploration of the trigeminal nerve was planned.

In the hospital, Ms. A was uncooperative and belligerent. She fought with nursing staff when they refused to give her narcotic medication in the dose that she had been taking at home. On the day before the scheduled surgery, she was angry and moderately depressed and talked openly of suicide if the surgical procedure was not of benefit. That evening, she was combative, confused, and disoriented and seemed to be hallucinating. She was transferred to a psychiatric hospital and treated with major tranquilizers. Approximately 6 days later, she experienced remission of her psychosis and complete relief of her pain.

During the course of her psychiatric admission, the patient was found to be more angry and more depressed than she had been before. She was the youngest child in a family of four significantly older siblings. Her mother was deaf by the time the patient was 7 years old and her father, whom she described as a handsome, successful businessman known about town for his extramarital affairs, was away from home often. Although the mother knew of his affairs, she attempted to deny them. The patient idolized her father and was unaware of his affairs until she was 12 years old, when she discovered a card sent to him by another woman. She showed the card to her mother, and soon after a confrontation the parents separated and subsequently divorced. Shortly after the divorce, her father announced that he planned to marry the patient's second cousin, who was only 10 years older than Ms. A. Her mother became quite upset and was hospi-

talized for depression. Ms. A was immediately placed in a girls' school in another state, where she had little contact with her parents. She became isolated and lonely and turned to other girls for companionship, later entering into a homosexual relationship with a teacher who, she felt, treated her in a motherly way and supplied many of her affectional needs.

After graduation, Ms. A obtained a position as an airline stewardess and became quite successful. During this time, she had an affair with a man who reminded her strongly of her father. She became pregnant, but the man was married and refused to leave his wife. Ms. A took a leave of absence and returned to her family home. Both of her parents suggested that she have an abortion, but she refused on religious grounds. Her mother consented to keep her at home if she agreed not to show herself outside the house. Relatives and neighbors were told she was away on vacation. At the time of delivery, she went to a hospital in another area under an assumed name. Arrangements were made for the child to be adopted. However, after she convinced one of the nurses to show her the baby, a healthy male child, she had second thoughts. Her father persuaded her to go through with the adoption.

When she returned to work, she met a woman her age—an alcoholic nightclub singer, who became her roommate and then her lover. Ms. A soon discovered that her roommate was seeing other women; eventually her roommate left her for another woman. Ms. A became severely depressed; she coped with her depression by involving herself in a homosexual community, where she had no serious relationships. She suddenly developed severe jaw and mouth pain and consulted a dentist, who restored several carious teeth. This pain was similar to that which eventually led to her hospitalization but disappeared when the patient became seriously involved with another airline stewardess, who was an alcoholic. This relationship ended much as the previous one had, and the jaw and dental pain returned.

The patient was promoted and left flying status to return to her native city. She established herself in a homosexual community and developed two more serious relationships with alcoholic women, which ended like the earlier ones. She was hospitalized for a definitive pain procedure during another serious relationship with an alcoholic woman who physically abused her. When Ms. A ended the relationship because of her lover's drinking, the pain became so severe that she considered a definitive procedure. In subsequent interviews, it was discovered that the patient's father had died as a result of alcoholism.

Case 2. Ms. B is a 60-year-old woman who presented to the neurosurgical service for posterior fossa exploration for left trigeminal neuralgia. She had had left-sided facial pain for 3 years, beginning with sharp intermittent pain over the V_2 and V_3 distribution. The pain gradually became constant and radiated over the entire left side of her face. She was seen by physicians at several neurologic centers and was placed on diphenylhydantoin without significant results. Later she was given carbamazepine, which produced little relief and caused depression in her peripheral white cell count. Ms. B was referred to an oral surgeon, who removed the left mandibular teeth and resected the left lingular nerve. She still had mandibular pain that now radiated into her lower lip as well as over the entire left side of her face. She also complained of extreme sensitivity in her mouth and was unable to wear her bridgework. Physicians at the Pain Clinic attempted to inject the trigeminal nerve, but this gave the patient no relief. Ms. B was addicted to barbiturates for sleep and lost 22 kg because of her poor eating habits. Just before the facial pain started, she had undergone a left radical mastectomy for carcinoma; she was 5 years postoperative at the time of admission and free of metastatic disease.

On the night before her scheduled pain surgery, a resident found Ms. B in her room with her arms folded across her chest. She said that she was dead and wanted her husband to be at her funeral. She was disoriented, confused, and grossly hallucinating. She was transferred to the psychiatric hospital and treated with major tranquilizers. The psychotic symptoms disappeared within two days, and she did not complain of facial pain while on medication.

History revealed that Ms. B had led a very sheltered life, protected by both parents from even minimal stresses. When she was in her twenties she married a man several years older. She never assumed any responsibility for making decisions in the marriage, and her husband also assumed much of the responsibility and care for their three children. During the last 6 years of their marriage, the husband had a senior executive position and made many trips away from home. At this time, the older children were married and the youngest son was at school. The patient was alone for long periods of time and was unable to make any decisions concerning even minor household tasks without consulting her husband or family. She turned to club work and to organizations where she could spend most of her days in structured activities.

After the mastectomy, Ms. B was confined at home for a long time and spent most of her recuperative period alone. The facial symptoms were first noted at this point. When the facial symptoms recurred 5 years later, the patient was again able to regain family interest and concern and her husband and children were obliged to spend more time with her than they had previously. There was no indication of childhood or adolescent facial symptoms.

Case 3. Ms. C, a 56-year-old woman, was transferred to the neurosurgical service for posterior fossa exploration of the left trigeminal nerve. The patient gave a 3-year history of left-sided facial pain, primarily in the V_2 and V_3 distribution, which gradually became generalized to the entire left side of her face. The pain was throbbing at first and then became constant. She soon began to use narcotic medication during the day and barbiturates at night. A number of dental surgeons had recommended that most of her lower teeth be extracted. This provided temporary relief, but the pain resumed several months later. The upper teeth were then extracted, with similar results. Most of the time she was unable to wear her dentures. Ms. C was followed in another city and had a series of nerve blocks, all without results. Because of the progression of the pain, she was transferred to the neurosurgical service for a definitive procedure.

On admission, she appeared to be very pleasant and got along well with the house staff and nurses on the neurosurgical unit. She expressed interest in the procedure and hoped it would end her pain. The night before the scheduled surgery, Ms. C began talking to the nursing staff and others about her family. She said that she and her husband had been married for many years but had never been close. Her husband had been a long-distance truck driver and was known to have frequent affairs; Ms. C felt this was simply an "occupational hazard." She had always been faithful. They had two daughters, the older of whom became pregnant a year before the patient's facial pain began and married against her parents'

wishes. After the daughter's marriage, Mr. C had a myocardial infarction and had to quit driving and take a less lucrative job in the office. It was necessary for Ms. C to go to work as a waitress in a local restaurant.

Although she had established some degree of closeness with her daughter and son-in-law, Ms. C felt that she had never really forgiven her daughter and blamed her for Mr. C's myocardial infarction. The day her surgery was scheduled was the birthday of the second daughter, who was now the same age the older daughter had been when she became pregnant. The night before the scheduled surgery, Ms. C was confused, crying, agitated, and hallucinating. She believed that she had killed her husband and her granddaughter. She was transferred to a psychiatric hospital where she was treated with major tranquilizers for one day and then was transferred to a hospital in her home city at her family's request. Follow-up revealed a 2-month hospitalization with continued administration of major tranquilizers and complete remission of psychosis. Six months after discharge, she had had no further incidents of the facial pain.

FOLLOW-UP

Ms. A and Ms. C were followed for 18 months after their initial hospitalizations and have continued taking major tranquilizers and antidepressants, with no recurrence of the facial pain. Ms. B went out of the country on vacation with her husband and did not take her medication for approximately 30 days. The facial pain returned, but not with its initial severity. When she resumed her medication, the facial pain disappeared and has been in remission since that time. Ms. C was not followed directly, but reports from her physician indicated that she had had no further complaints of facial pain. Ms. A and Ms. C have had no further treatment of the facial problems other than normal dental care and have been able to tolerate repair of carious teeth and prophylaxis. They are now seen twice a month for half-hour interview sessions. The therapy is supportive and semidirective and the patients know that they can contact their physicians if necessary. Neither patient has expressed any interest or concern about recurrence of the pain or about medical or surgical therapy.

DISCUSSION

The three patients I have described are similar in many ways—all are women over 40 who had facial pain for several years and underwent multiple oral surgical or medical treatments. Treatment usually provided brief periods of relief, but symptoms returned rapidly. In case 1, symptoms were related to increases in stress.

All of these patients had striking psychopathology in their histories. Ms. A's history included overt orality and unresolved oedipal conflicts that were reflected in the patterns of her adult life. Her facial pain emerged when these patterns were unable to meet her needs. The patient could not focus her attention on the pain, which served as an "emergency discharge" (7) for tensions raised by more serious intrapsychic conflict. The pain provided a rational basis for her expressions of anger and bitterness.

Simultaneously, Ms. A achieved relief of guilt by using her discomfort in a self-punitive way. The pain then served to mediate the delicate balance between function and complete ego disintegration. In order to ensure the validity of the defense, she had to search continuously for a cure for her discomfort. Temporary reinforcement brought about temporary relief, but surgery threatened this balance and ensured complete ego destruction. Even the threat of surgery was sufficient to produce an overt psychiatric episode: reintegration was rapid once the threat was removed.

Similar mechanisms are involved in the case of Ms. B, whose extreme dependency was no longer satisfied when her children left the home and her husband's job required him to be away much of the time. Her inability to adapt was further stressed by her mastectomy, which added a physical limitation to the system. Her internalized fear of dying was then externalized as an actual life-threatening disease. The resurgence of input from her family, who rallied around her during her illness, temporarily maintained her ego balance. As she improved, family members withdrew their attention and returned to their own activities, leaving the patient to cope with her inadequate defenses. She soon developed the facial pain which, as in case 1, lasted as long as the balance was not disturbed. When surgery threatened to remove the pain, ego disintegration occurred. Again, reintegration was rapid when the threat was removed.

In the case of Ms. C, the pain served to drain off tension resulting from the family structure. The past infidelity of Ms. C's husband, his myocardial infarction, and her daughter's pregnancy all proved to the patient that she was worthless. She could not allow herself to feel anger for fear of complete loss of her family. The pain established value in her life; by constantly rising above it, she gave some credibility to her existence. The increasing frequency and severity of the pain were directly correlated with the approach of the younger daughter's birthday and the fear that the older daughter's situation would be repeated. When threatened with removal of the escape valve (her pain) by surgery, the system gave way to overt psychotic behavior.

In all three cases, the facial pain became the major symptom of the underlying psychopathology. As long as this symptom held and could be compartmentalized, the patients continued to function. The defensive nature of this symptom became evident when there was a major attempt to remove it surgically. Constricted ego function with little latitude for movement is suggested in all of these cases. The pain represented the major symptom of the disturbance and served as an emergency discharge that prevented disintegration. When threatened, the entire defensive structure collapsed and the psychosis emerged. There can be little doubt from these histories that the patients' psycho-

pathology had existed long before the facial pain appeared.

CONCLUSIONS

In this paper, I have described three cases in which I believe the major intrapsychic conflicts were expressed by atypical facial pain. Orality was a major feature of the psychic structures of these patients, and it is interesting that a facial symptom was chosen for its expression. The pain was the major presenting complaint of the underlying emotional disturbance, and the threat of its removal caused overtly psychotic behavior to surface. Treatment with antipsychotic drugs and psychotherapy resulted in disappearance of the psychotic symptoms and when reintegration occurred there were no further complaints of pain. However, when therapy was discontinued for a brief period in case 2, the symptoms began to return.

Lead and Hyperactivity. Behavioral Response to Chelation: A Pilot Study

BY OLIVER J. DAVID, M.D., D.M.SC., STANLEY P. HOFFMAN, PH.D., JEFFREY SVERD, M.D., JULIAN CLARK, M.D., AND KYTJA VOELLER, M.D.

Lead-chelating medication was used to treat 13 hyperkinetic school children whose blood and urine lead levels were in an elevated but "nontoxic" range. Six children with histories of etiologically relevant perinatal or developmental complications showed relatively little improvement. Seven other children with unremarkable histories, and for whom a lead etiology could thus be entertained, showed marked improvement. The authors conclude that lead may play an important role in the etiology of some cases of hyperactivity; lead-chelating agents may have a major place in the treatment of hyperactivity; and the medical workup of hyperactivity should include lead level measurements and careful consideration of other possible etiological factors.

VARIOUS TOXINS existing (and increasing) in the environment have deleterious effects on the central nervous system (CNS) that may range from severe organic destruction to subtle brain dysfunction (1–3). In an earlier report (4) we drew attention to the presence of raised levels of lead among hyperactive school children. Approximately 50% of those whom we examined had lead levels in an elevated but "nontoxic" range (25–40 μg/100 ml of blood). A more recent study (5) indicated that when a likely cause for hyperkinesis existed (other than a lead-related one), lead levels were significantly lower than in those children in whom there existed no known likely cause for the hyperactivity. These studies lend weight to a hypothesis that states that chronically elevated but "nontoxic" lead burdens may be directly etiological in some cases of hyperactivity.

In order to explore this hypothesis, we are using chelating medication in the treatment of hyperactive children with elevated lead levels. If these high levels are causally related to hyperactivity, lowering them should ameliorate the condition. This preliminary report derives from the previously cited study. Drawing on the first 13 children to complete that treatment regimen, we compared the effects of deleading in the following two groups: 1) those children in whom a probable other cause for hyperactivity existed (as a group they usually show normal lead levels, but exceptions obviously exist), and 2) those children in whom there was no other known cause for hyperactivity. If an elevated lead level is etiological in some cases of hyperactivity, deleading should be most effective in the latter group. We assert this because they have no other known cause for hyperkinesis in their history, and as a result only lead remains as a possible etiology. Deleading therefore relates directly to the only "cause" in this group. In the probable-cause group, the other nonlead-related etiology remains after the deleading and will continue to exert its effect. Therefore only minimal alteration in hyperactive behavior is to be expected in this group.

METHOD

Subjects

The children in this series were referred to our unit for the diagnosis and treatment of hyperactive behavior. At the initial interview the purpose and scope of the research project was carefully explained to the parent. If the parent agreed to participate, formal written consent was obtained.

Acceptance into the research protocol required the establishment of a diagnosis of "hyperactive reaction of childhood." The reports of 3 observers—the child's teacher, parent, and doctor—were used. These reports and the manner of utilization were described in an earlier report (4).

Lead Levels

Admission to the research protocol required an elevated body lead burden defined as greater than 25 μg/100 ml of blood and/or 80 μg/liter of urine in a chela-

tion-provoked specimen. Methods of collection and the analytic methods used were also described in an earlier report (4).

Etiological Determinations

The intake procedure included a detailed medical history of the mother's pregnancy and delivery and the subsequent history of the child. On the basis of these, a judgment was made as to the presence of etiologically relevant events that alone might account for the child's hyperactivity. Children were classified according to whether there was evidence of a perinatal or developmental trauma known to affect the development and/or functioning of the CNS, e.g., birth weight of less than 2.27 kg or meningitis. On this basis 6 children were found to have a probable cause in their history. Seven children were considered to have no known probable cause. The reliability of this categorization scheme has been reported elsewhere (5).

Intergroup Differences

The relevant characteristics of the 2 groups are as follows. They ranged in age from 6 to 10½ years (mean = 8.2 years). There was no meaningful difference in age between the 2 groups. There were 2 girls among the probable-cause children and none in the other group. While there appeared to be no differences in urinary lead levels, blood lead levels were lower for the probable-cause children (22.5±6.4 versus 29.2±5.9). This difference is consistent with previous results indicating that lead levels are lower among children for whom other probable etiologies can be posited (4, 5).

Procedure

The treatment protocol for all children lasted 12 weeks. Active chelating medication was given for the first 4 weeks and discontinued for the following 4 weeks. If blood and/or urine lead levels available at the eighth week visit were at or above the intake level requirement, the child was given a second 4-week course of treatment with chelates. Otherwise, no additional chelating medication was used.

Two chelating medications, penicillamine and calcium disodium edetate (CaEDTA), were used. All children who were not known to be allergic to penicillin were given penicillamine in capsule form, prescribed at a fixed dose of 250 mg twice a day. Two children, 1 from each group, were allergic to penicillin. No penicillamine was used in these cases. They were both hospitalized in the Clinical Research Center at the State University of New York, Downstate Medical Center, for the first 4 days of the 12-week treatment period, during which time they received the following: one intramuscular dose of 50 mg/kg of CaEDTA and, for the rest of the hospital stay, an oral dose of 500 mg of CaEDTA twice a day. On discharge, they were treated with oral doses of 500 mg of CaEDTA twice a day in exactly the same fashion as the penicillamine-treated children. In addition to receiving chelating medication, 4 children (1 in the no-known-cause group and 3 in the probable-cause group) were also given methylphenidate throughout the entire 12-week treatment period. They were started on a very low dosage (5–10 mg/day) to minimize side effects and thereafter were treated according to the order of the treating physician, up to 40 mg/day.

The assessments presented are those obtained during a drug-free baseline period and those taken at the end of the 12-week treatment period. The following scales were used: A teacher rating scale (6), a parent symptom questionnaire (7), a hyperactivity checklist (8), and a clinical global impression scale (9).

RESULTS

Figure 1 presents the mean blood lead levels for the 2 groups over the 12 weeks of treatment. As can be seen, there was a sharp drop for both groups by the end of the 4-week treatment period. This occurred in every child. When the medication was removed, blood lead levels rose, approaching but not reaching the baseline levels. The decline from week 8 to week 12 reflects the fact that 5 of the 7 children in the no-known-cause group and 3 of the 6 children in the probable-cause group resumed chelation treatment. By the end of the 12 weeks of treatment all but 1 of the children showed blood lead levels that were significantly lower than their baseline values. The average decrease in the no-known-cause group was 9.9 μg/100 ml, and in the probable-cause group, 4.5 μg/100 ml. The difference between the 2 was not statistically significant ($t=1.71$, $p<.20$).

By most indications the effects of chelation treatment were different for the 2 groups. Children with no known cause in their history for hyperkinesis seemed

to show considerable improvement, whereas the probable-cause children seemed to profit little. These differential treatment effects were apparent in one or another aspect of the ratings by the teachers, parents, and doctors.

Teacher ratings indicated improvement in hyperactivity and conduct disturbances for the no-known-cause children but little or no change for the probable-cause group (see table 1). Indeed, the week 12 ratings on the hyperactivity factor of the teacher rating scale were below the intake requirement (1.5) for all but 1 child in the no-known-cause group but at or above that level for all children in the probable-cause group.

Ratings by the parents on the parent symptom questionnaire and the hyperactivity checklist gave evidence of widespread improvement in the behavior of the children in the no-known-cause group, which in all but one instance was significantly greater than the changes registered by the parents of the children in the probable-cause group (see table 2). There was a significant reduction in both groups on the hyperactivity checklist. However, the week 12 ratings on this scale

were below our intake requirement (2.0) for all but 1 child in the no-known-cause group but above that level for all but 1 child in the probable-cause group. Thus a trend was also apparent on this rating scale as well.

The doctors' ratings similarly reflected greater improvement in the no-known-cause group. Five of the 7 children in this group were judged to be "much" or "very much" improved, compared with only 1 of the 6 children in the probable-cause group. The doctors' mean ratings of "severity of illness" went from 3.7±0.5 to 1.9±0.4 for the no-known-cause group ($t=7.21$, $p<.01$), while the mean ratings for the probable-cause group began and ended at 3.8 (SD=±0.5 and 1.0).

DISCUSSION

Most authorities agree that hyperactivity is a symptom state resulting from a multiplicity of causes. This study has been directed at examining the possibility that one of them might be a long-standing, mildly increased lead burden in susceptible children. Our findings indicate that with a child whose hyperactive state is not known to be due to any of the common and/or known etiologies, and who also has a slightly increased body lead burden, treating the condition of the increased lead burden with chelating agents markedly ameliorates the hyperactive condition. In other words, when the lead-hyperactivity association is broken by removing the lead, hyperkinesis also seems to diminish. The findings also indicate that when a hyperactive child with a probable cause for his hyperactivity has an elevated lead level, little or no improvement results from chelation treatment. We feel less sure of this latter conclusion because of the sex variability among the probable-cause children and also because of their initially lower baseline blood lead levels.

It will be noted that our results include 1 child in the no-known-cause group and 3 children in the probable-cause group whose scores reflect both chelation and methylphenidate treatment. We would point out that methylphenidate is an effective treatment for hyperactivity, so that if anything, an improvement in the probable-cause group would have been effected to a much larger extent than the no-known-cause group, as more children in that group received both medications. Not using methylphenidate would only have served to widen the behavioral differences between the 2 groups at the end of the chelation period.

Although the use of this criterion is increasingly questioned, 60 μg of lead per 100 ml of blood is usually considered diagnostic of poisoning. In fact, this criterion is quite arbitrary and is based historically on the correlation existing between that lead level and obvious symptoms of poisoning. We have used 25 μg of lead per 100 ml of blood as our primary criterion for treatment. Approximately 50% of the hyperactive children seen have thereby qualified for treatment, and of these more than half showed a marked amelioration in problem behavior over the course of the deleading regimen. Although these findings need more controlled replication, we believe they argue strongly for a significant modification in the lower limits of what is considered lead poisoning. Just as importantly, these findings seriously challenge the threshold concept of lead poisoning.

We conclude this discussion with the observation that there are some children who appear to be unaffected by massive lead levels, i.e., 90–100 μg/100 ml (10). Our work indicates that there are others in whom a relatively small blood lead elevation appears to have a profound effect. It therefore seems obvious that host resistance is a major factor in this complex interplay and should be carefully considered in the promulgation of health regulations.

Impact of a District Branch Task Force on Women

BY ELAINE HILBERMAN, M.D., MARIA GISPERT, M.D., AND JACKIE HARPER

A questionnaire sent to all women psychiatrists and trainees in North Carolina as part of the development of a district branch Task Force on Women indicated that institutional sexism affects the careers of many of the respondents. Problems of family-professional role conflicts were especially pronounced in residents and faculty women. Survey findings have resulted in recommendations in the areas of education, communication, and increasing women's participation in task force and district branch activities. The authors feel that such task forces provide a much needed network of supportive relationships for women psychiatrists and raise the consciousness of the district branch regarding women's issues.

In 1972 the American Psychiatric Association created a Task Force on Women, which was charged with exploring the concerns of women in psychiatry and the relationship of psychiatry to the problems of women in general (1). These goals were accomplished in several ways, including the establishment of informal communication networks for women psychiatrists at the grassroots level and programs about women at annual meetings of the Association. The strong and visible presence of the APA Task Force on Women provided invaluable support to women psychiatrists around the country, who often had been quite isolated from each other and from their male colleagues. One impact of this support system was the spontaneous appearance of local task forces on women as part of district branch activities. A panel at the 1975 annual meeting (2) described the development of a variety of local task forces on women, which differed as a function of geographic location, constituency, perceived needs, and level of feminist consciousness. Perhaps the one common feature was that the leadership of each task force was always shared by two women, who were able to give each other the necessary support to confront the male-dominated district branches. This report will describe the work and impact of one such local task force in the 2 years since its inception.

The North Carolina Neuropsychiatric Association (NCNPA) is a district branch of the American Psychiatric Association and draws its membership from the entire state. The association has a total membership of about 300, 10% of whom are women. The members are separated by geographic distances as well as a wide spectrum of professional interests. There are semiannual meetings; spring meetings are poorly attended, and fall meetings are moderately well attended by academicians or practitioners, depending on program content. Partly because the leadership of the NCNPA is male and appointments to committees are usually made by personal contacts, the executive and policy making bodies of the association have not included women, and formal programs have reflected traditional interests and values. Several women stated that they had not been asked to participate and hesitated to volunteer because the all-male composition of committees made them feel unwelcome. Further, personal communications to task force members have revealed that women psychiatrists eligible for APA fellowship status have been dissuaded from applying or have been given weak recommendations at the district branch level.

In May 1974, the NCNPA created a Task Force on Women as the result of a direct request made by the two women psychiatrists who subsequently chaired the task force. Once formal task force status was conferred, it was decided that a survey of women psychiatrists in North Carolina should precede both expansion and definition of goals for the task force. The primary purpose of this paper is to present the findings of this survey and their implications.

METHOD

The survey was accomplished by means of a lengthy questionnaire which incorporated material used in a questionnaire developed by the APA Task Force on Women. The questionnaire was mailed to all women psychiatrists and psychiatrists-in-training in the state, regardless of membership status in the NCNPA. One section of the questionnaire dealt with general issues relevant to women and was sent to the entire sample,

Dr. Hilberman is Assistant Professor and Dr. Gispert is Associate Professor, Department of Psychiatry, University of North Carolina School of Medicine, Chapel Hill, N.C. 27514. Ms. Harper is Executive Secretary, North Carolina Neuropsychiatric Association (NCNPA). Drs. Hilberman and Gispert cochaired and Ms. Harper was a member of the NCNPA Task Force on Women. Dr. Hilberman now chairs the NCNPA Committee on Women and is Vice President of the NCNPA, and Dr. Gispert is Secretary of the NCNPA.

The authors would like to thank the American Psychiatric Association Task Force on Women for permission to use sections of their questionnaire and Anne M. Seiden, M.D., for her assistance in developing the questionnaire used in this study.

while other sections were specifically designed for women in training, private practice, on university faculties, or employed in hospitals or mental health centers.

RESULTS

Of the 50 questionnaires mailed, 25 were completed and returned. A summary of the responses follows.

Demographic Data

The 25 respondents were distributed by professional categories as follows: private practice, N=8; hospitals or mental health centers, N=3; trainees, N=8; and faculty members, N=6. Response rates were 60% for women employed in academia and in hospitals or mental health centers, 50% for private practitioners, and 42% for trainees. The respondents ranged in age from 26 to 77, with a fairly even distribution from the mid-twenties to sixty. Sixty-four percent were married and 36% were single, divorced, or widowed. Respondents had a total of 45 children, with a range of 0–4. Patterns of early childrearing practices of the 17 women with children varied with the age of the respondent. Younger women reported taking less than 6 months off for childbearing and child rearing, while those over the age of 45 had spent an average of 6–8 years away from their careers. Sixty-four percent of the sample had full- or part-time household help.

Seventy-two percent of the sample were working full-time and 28% part-time. Full-time work was defined by the respondents as 36–65 hours a week and part-time work as 10–35 hours a week. Respondents reporting part-time work included all settings other than academia. A broad spectrum of professional interests was reported, with a special interest in children and adolescents mentioned frequently by faculty women and trainees. Few women described any serious research interests. Specialty training was reported by 44% of the sample, but only 25% were Board certified. Failure to take the Boards was usually attributed to insufficient time for preparation as a result of dual commitments to family and career. The respondents tended to be joiners of professional organizations: 76% belonged to the NCNPA/APA, 48% to the American Medical Association, and 36% to the American Medical Women's Association.

Training

The majority of the respondents believed that seminars on women's issues, women's studies, courses, and a format to deal with family-career conflicts are important parts of psychiatric education. Responses indicated that these perceived needs had not been met in respondents' training in the past and continue to be unavailable for the present group of trainees. It is interesting that 60% indicated that they had adequate supervision and teaching by women psychiatrists and 88% believed that there were women available with whom they could share personal concerns about their roles. However, more than half of these affirmative responses were qualified; for example, respondents noted that there was no time set aside in program priorities to deal with role conflict or that only nonphysician women role models were available. Also, one faculty woman was mentioned by several respondents as being the only woman available to trainees.

Patient Care

Questions in the patient-care section dealt with the availability of women therapists, of therapists sensitive to role conflict and to assumptions about mental health based on sex-role stereotypes, of crisis intervention for rape victims, counseling for problem pregnancies, abortion counseling, support for decisions to terminate marriage, and nonjudgmental treatment of lesbians who do not wish to change their sexual preference. The data were strikingly inconsistent—for example, several women who indicated that they were the only women therapists in their geographic areas or academic institutions also believed that availability of women therapists was adequate. Some women did not think it was important for therapists to be sensitive to role conflict. One woman was unaware of the existence of stereotypic assumptions about mental health based on sex role. Almost two-thirds indicated that there had been no discussion in their work settings about issues regarding the treatment of women as patients. The responses suggest that although there is a growing awareness of changes in women's roles in contemporary society, women in psychiatry are not as sensitive as they might be to the needs of women patients.

Women's Movement

Questions in this section were related to impressions of and degree of involvement in the women's movement. Eighty percent expressed favorable feelings about the women's movement. Of this group, however, only 30% described strongly favorable feelings, while 70% indicated milder interest. Uncertainty about the goals of the movement was illustrated by a respondent who was favorable toward it but was "more interested in economic discrimination." One of the less interested respondents commented, "Since I personally never had problems in these areas, it seems that time is better spent in developing one's professional skills." The majority were aware of the concept of consciousness-raising groups, and 24% indicated that they refer patients to such groups. Most favored passage of the Equal Rights Amendment; a few were ambivalent. Although many respondents joined professional organizations, they tended to be nonjoiners of organizations related to the women's movement. The high percentage of positive responses to the women's movement may reflect a skewed sample. We assume that women who took time to complete the questionnaire had more sensitivity to issues of sex role stereotyping and sex discrimination than nonrespondents.

District Branch Activities

Seventy-two percent of the respondents thought that the NCNPA should take a formal, affirmative position with regard to the Equal Rights Amendment, which was at that time being debated in the state legislature. Although most respondents were aware that there have been no women in important policy making or executive positions in the NCNPA, 56% were not interested in increasing their activities in a leadership position, 24% expressed an interest in doing so, and 20% were undecided. Less than half believed that the NCNPA programs adequately reflected concerns of women psychiatrists and problems specific to women patients. They suggested a variety of themes for future programs, including women in residency training, sex roles and children, early training to help women keep options open in future roles, treatment of women patients, lesbianism, and rape. Despite respondents' minimal interest in increasing their participation in district branch activities, over half of them said they would take part in a panel or program about women. The majority thought the existence of a Task Force on Women was relevant and necessary, but only 28% indicated willingness to participate actively.

Individual Work Settings

The following section summarizes responses of women regarding their various professional settings.

1. Private practice. Four of the private practitioners were in individual practice and 4 were in group practice. Their primary activities were individual psychotherapy and consultation. However, all 8 had teaching responsibilities, some of them quite substantial, at nearby teaching institutions. They expressed satisfaction with relationships with male colleagues, whom they described as supportive, and with quality and quantity of patient referrals. Only 3 of these women indicated that they had engaged in any discussions in their work setting about the needs of women patients. Those in group practice had discussed attitudes about working women with their groups before joining. In general, they had fewer complaints and indicated less conflict about roles than did women in the three other settings. Their responses suggested that they had chosen the private practice setting in order to increase flexibility of scheduling and to facilitate family commitments.

2. Hospitals or mental health centers. One of the 3 respondents who worked in this type of setting described overt discrimination in hiring practices, promotions, and salaries and characterized her relationship with male colleagues as "indifferent." The other 2 women described their status as "equal among equals," with no institutional practices discouraging women, but they also reported no provisions other than paid leave based on accumulated leave time to deal with childbearing and child rearing, nor were there special arrangements for night calls, weekends, or vacations for staff members with families. No ombudsperson was available to these women in cases of perceived sex discrimination, and there was no grievance procedure available to 2 of these 3 women. All 3 respondents in this category indicated that there had been no conferences or seminars on the psychology of women, sex roles, etc., at their facilities. While it is not possible to draw conclusions based on a sample of 3 respondents, the lack of flexibility in procedures related to childbearing and child rearing and on-call scheduling indicates subtle institutional sexism of which some women were unaware.

3. Trainees. The 8 trainees described their residency training experiences with frustration and cynicism. They were all in programs with few other women and knew very little about affirmative action programs, recruitment policies, child care arrangements, and grievance procedures in their programs. There were no special arrangements for night call, and part-time training opportunities were difficult to arrange. Provisions for childbirth and child care were generally handled on an individual basis, usually involving paid leave based on accumulated sick or vacation time, with no credit for time in residency. In contrast, in one program there was a formal policy whereby short military leave (e.g., 2 weeks a year in the reserves or the National Guard) was fully paid, did not come out of accumulated leave, and did not lengthen residency training time.

Most of these respondents had no ombudsperson available to deal with any perceived sex discrimination, and 7 of the 8 were not aware of any formal grievance procedure. The one resident who did report the existence of a grievance procedure summarized it as follows: "You end up going to the chairman and if he agrees, you may succeed. If he doesn't, that's it." Financial issues were mentioned often. One woman stated, "Salaries are too low to permit adequate household help to make life bearable while in training." All but one respondent indicated that faculty women were not adequately represented in positions of power at their various institutions.

The information we gained about the content of training was equally disheartening. Most residents reported that less than 10% of their course work, seminars, and supervision was conducted by women, and courses and seminars about women were strikingly absent (e.g., "minimal amount—one seminar during first year of residency"; "adherence to old Freudian psychology—just lip service to treating women as people rather than as castrated men").

Some other comments by women residents included the following:

> I have felt a double standard in my training. If I work extremely hard, I do not have to worry about overt discrimination from the faculty. There is infantilization of women by some and a true lack of understanding by most.
>
> Most [peers] pay little attention to me. They seem to relate to each other as boys only, i.e., sports and poker.
>
> [Relationships with peers] good at present, with some

distance and difficulties around competition . . . many feelings about women in their past placed on me in concentrated form and very unpleasant.

4. Faculty. The 6 faculty respondents were quite similar to the trainees in their expressions of frustration, but they had more specific information available to document seemingly pervasive patterns of discrimination and isolation. Personal contacts—the "buddy system"—seemed to be the prevalent mode of faculty recruitment, with 4 of these 6 women indicating that search committees rarely included women and that open advertising is rare. Only one woman had access to salary information, and there was considerable uncertainty about how these respondents' salaries correlated with those of male peers. One woman reported having been "openly told I would receive less because I was married to another faculty member." Part-time faculty appointments were rare and did not lead to eventual tenure. Provisions for childbearing and child rearing were uncertain, and it is relevant that few faculty women had small children. None of the faculty women indicated the availability of an ombudsperson or of an adequate grievance mechanism for issues of sex discrimination.

Formal discussion about the status of women psychiatrists was reported to be infrequent. In contrast to the women residents' reports of the powerlessness of female faculty members, the women faculty perceived themselves to be adequately represented in positions of power. Course work and seminars specifically on women's issues were absent; such material was only brought up indirectly in an occasional seminar.

Faculty women made the following comments about problems in their departments: "Integration of professional life with family and/or private life has presented problems for almost every woman in differing degrees." "Lack of power, isolation of women from male faculty, and rigid expectations that a successful woman must act like a man to survive in the department." "Not enough time; academic pressure towards productivity and performance. Women who are offered positions only stay from one to four years because of the stress of the academic environment."

TASK FORCE RECOMMENDATIONS

A summary of questionnaire results was presented to the membership at the fall meeting of the NCNPA in October 1974, and the following formal recommendations were offered:

1. Despite the burdens of dual roles, women must become active on their own behalf, as advocates for women patients, and as role models for men and women trainees.

2. The NCNPA has a responsibility to become sensitized to the needs of women members in the areas of both educational programs and appointments. A generous portion of the 1975 fall meeting might appropriately be devoted to a theme of particular relevance to women in psychiatry.

The report and recommendations were surprisingly well received, partially because this is an area of growing interest. In addition, the organization was facing an energy crisis in which apathy and insufficient commitment to maintain the organization prevailed. The Task Force on Women was proposed and perceived as one mechanism for bringing a new level of interest, activity, and membership to the entire organization. The final report of the American Psychiatric Association Task Force on Women recommending a standing committee on women was also introduced and added credibility to the local task force report. As part of the fall meeting, the NCNPA task force held an open meeting for women members, at which time our membership was expanded.

IMPLEMENTATION AND IMPACT

The following section summarizes the work of the Task Force on Women to implement their recommendations.

1. *Participation.* A mailing was sent to all women members, asking about their interest and availability in serving on the various committees and components of the NCNPA, and the responses were forwarded to the district branch President. Questionnaire responses had indicated that few women would accept an appointment, so it was particularly gratifying that almost half of the female membership agreed to serve on committees. We believe that the questionnaire itself may have served an important consciousness-raising function. One of the cochairpersons of the task force was elected to the Executive Council of the district branch and was the first woman to serve on that council in many years. Women have subsequently been elected to several other positions on the Executive Council and are now represented on almost all committees of the NCNPA.

2. *Communication.* Because the district branch encompasses the entire state, meetings have not seemed a workable vehicle for communication, and the NCNPA newsletter has been used to disseminate information about women to the membership. There was, for example, an entire page on the Equal Rights Amendment, including a statement of APA's position, which led many members to contact their legislators.

3. *Support.* Although few of the women psychiatrists have expressed interest in an ongoing consciousness-raising group, task force meetings always seem to go far beyond the stated agenda; personal and professional conflicts are often presented with urgency and a flood of relief. This phenomenon documents the extent to which these women have been isolated from their peers and their need for support from women colleagues. For example, several articulate and talented women who were invited to participate in the NCNPA fall meeting refused because they felt they had little of

value to communicate to their colleagues. It is anticipated that continuing contacts among North Carolina's women psychiatrists will raise self-esteem as well as consciousness.

4. *Education.* The idea that a program about women was relevant and appropriate was accepted, and such a program took place at the 1975 fall meeting of the NCNPA. Fifteen enthusiastic women participated in a series of brainstorming meetings which resulted in more than enough material for a one-week program. The one-day program was entitled "Changing Images of Women" and focused on the concerns of professional women and the mental health needs of women patients. Issues about men's roles and the impact on men of the changing roles of women were also addressed. Although there is recognition that women psychiatrists have dual roles as professionals and wives and/or mothers, there has not yet been a full awareness of men psychiatrists' dual roles as professionals and husbands and/or fathers. Personal communications with male colleagues confirm that men also experience difficulty with time demands and role conflict.

The effectiveness of the task force was documented by the responsiveness of the NCNPA membership to the 1975 annual program. Full committee status was granted, with expansion of the Committee on Women to 15 members, including representation by spouses. The one-day program included formal presentations by women psychiatrists about supportive services for women medical students (3), women as residents in psychiatry (4, 5), psychotherapists' biases toward women (6) and research considerations by and about women (7). The evening presentation by a male historian (8) utilized a multimedia approach to describe the history and implications of the male sex-role stereotype and to evoke an affective response. The impact of the program was quite dramatic; both men and women psychiatrists and their spouses reconsidered their own roles as family members, parents, and professionals with thoughtfulness and poignancy.

In retrospect, we have theorized that the combination of cognitive input about women and the very evident cohesiveness and camaraderie shared by the women probably resulted in anxiety and a sense of isolation among the men, and the presentation about men gave them a voice with which to speak eloquently for themselves. Expressions of sadness and grief were universal as they talked about the pressures to be successful and the resulting estrangements from their families, especially their children. The meeting ended on a hopeful note, with considerable expressions of relief that there is more than one way to be a man or woman.

DISCUSSION

It is our impression that institutional sexism exists and directly affects the lives and careers of women psychiatrists in North Carolina, with the possible exception of those who choose private practice. Even in that setting, there are some women who would have preferred a major teaching role but found it to be incompatible with other responsibilities. Some women were aware of the institutional obstacles; others were not. Thus some respondents expressed satisfaction with their work settings while describing barriers to the full participation of women professionals. Women with young children seemed particularly sensitive to these deterrents, probably because younger respondents are more aware of social change and also face the realities of dual roles. One practitioner remarked,

> Those I know with no children express satisfaction and declare an absence of problems. Younger women have expressed stress problems pertaining either to husbands or children relative to the quantity of time together and deep concerns about failures of backup help with children.

Very few of the significant changes in the role and status of women throughout our society are reflected in current psychiatric education and training. Traditional values prevail, and there is little opportunity to discuss contemporary theories about the psychology of women, more appropriate treatment modalities for women patients, research efforts, and the role conflicts of women professionals. Role models for trainees continue to be unavailable because there are so few women in academic careers. Indeed, women in academia, both as faculty members and trainees, seem to be the most troubled about their careers and their families. As long as academic and professional requirements are presented in terms of male norms (e.g., the women respondents described part-time employment as 35 hours a week and full-time as 65 hours), women professionals will not be available as teachers, leaders, and role models.

Very few of the women who were sensitive to the issues we have discussed were participating in activities related to women, either in a professional role or as members of their communities, and few were actively involved with the district branch. The responses to a question about what these professional women believed were their most important sources of personal gratification are relevant to their tendency to be nonjoiners and nonactivists regarding women's issues: career and family were considered equally important, with over half of the respondents indicating (in this work-related questionnaire) that family came first. The tendency of the respondents to be nonparticipants may be in part a reflection of lack of awareness of the issues, but the reality is that time is at a premium, with career and family responsibilities leaving little energy for other activities.

CONCLUSIONS

The experience of the questionnaire and the existence of a visible and vocal group of women has served to raise consciousness among NCNPA membership

that women's issues, whether they relate to the role and status of women professionals, the treatment of women patients, or legislation determining social policy, are the legitimate and rightful concern of psychiatrists. We would like to reemphasize the fact that our local Task Force on Women would not have been possible without the strong leadership, encouragement, and support of the APA Task Force on Women.

Diazepam Treatment of Socially Isolated Monkeys

BY ADELE B. NOBLE, M.D., WILLIAM T. MCKINNEY, JR., M.D., CAROLE MOHR, AND ELAINE MORAN

Four rhesus monkeys were reared for the first eight months of life in total social isolation. One animal died during this period; the three remaining subjects were treated with diazepam in an isolation chamber, in their home cages, and in a playroom testing situation. Diazepam significantly decreased the self-disturbance behaviors of two subjects, and there was even the appearance of some social behaviors, although they were limited and not of the same quality as in nonisolated subjects. The authors discuss the implications of the data for understanding the significance of the social isolation syndrome in monkeys as a model for human psychoses.

SINCE THE EARLY 1960s it has been known that rhesus macaques that have been totally socially isolated for the first 6 months or more of their lives exhibit pervasive and persistent behavioral abnormalities (1). These behaviors include self-directed responses such as self-clasping, rocking, huddling, self-mouthing, and self-aggression. Age-appropriate social and environmental responses, such as social exploration and play, occur very infrequently in isolates. Until 1970 these abnormalities were viewed as permanent since rehabilitative attempts such as social exposure to peers (1), gradual adaptation to the environment (2), and aversive conditioning (3) were unsuccessful.

In 1970 Harlow and Suomi (4) achieved partial rehabilitation of 6-month total isolates by exposing them to heated, cloth-covered surrogates and then housing the animals in pairs. The rehabilitation was partial in that there were significant decreases in abnormal behaviors but only limited development of patterns of social interaction. However, this study did indicate that some rehabilitation was possible.

Two years later Suomi and associates (5) reported their most successful attempt at total rehabilitation. They employed younger monkeys as social "therapists" for the 6-month total isolates, and the isolates showed virtually complete recovery. Their self-directed behaviors decreased to insignificant levels, and their social interactions made them indistinguishable from their therapists.

Novak and Harlow (6) repeated the study with 12-month total isolates. Using environmental adaptation, self-pacing of visual input, and younger stimulus monkeys, they again achieved total rehabilitation. They concluded that all three modes were necessary to totally rehabilitate isolate monkeys. They said that "development of social behaviors in isolate-reared monkeys depends upon techniques that reduce anxiety in the new situation, that subsequently reduce interfering behaviors, and that promote the desired positive behaviors" (6, p. 461).

Exploring the possibility that drug treatment alone, without social stimulation, might effect change, McKinney and associates (7) used chlorpromazine to treat four 2½-year-old rhesus macaques that had been reared for the first 12 months of life in partial social isolation. These animals had high levels of self-disturbance behaviors, which had persisted since their removal from isolation. While these behaviors decreased significantly in 3 subjects, recovery was only partial since, as was the case with the surrogate-rehabilitated animals, the appearance of complex social behaviors was very limited. While this study generated much interest in the possibility of drug treatment of the isolation syndrome, it raised several questions.

1. Would rehabilitation attempts with drugs be more successful if they were initiated earlier, i.e., at or prior to termination of the period of isolation, rather than after the abnormal behaviors were well established?

2. Would the response to chlorpromazine be duplicated by the use of antianxiety drugs that did not have antipsychotic properties? Novak and Harlow's conclusion (6) that reduction of anxiety is essential in the treatment of social isolates supports the hypothesis that any agent which reduces anxiety would effect some degree of rehabilitation.

Revised version of a paper presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

At the time this work was done the authors were with the University of Wisconsin, Madison, Wis. 53706, where Dr. Noble was Child Psychiatry Fellow and Dr. McKinney is Professor and Chairman, Department of Psychiatry, and Director, Wisconsin Psychiatric Research Institute of the Medical School. Ms. Mohr is Laboratory Technician, and Ms. Moran is Research Specialist, Primate Laboratory, Department of Psychology. Address reprint requests to Dr. McKinney.

This work was supported by Alcohol, Drug Abuse, and Mental Health Administration grant MH-21892 and Research Scientist Development Award MH-47353 (to Dr. McKinney) from the National Institute of Mental Health and by the Wisconsin Psychiatric Research Institute.

Diazepam was supplied by Hoffman-La Roche Laboratories, Nutley, N.J.

3. Would response to the drug maintain itself through a challenge with socially adequate peers?

In this paper we report the results of the first part of a two-part study designed to address these questions. This study, which addressed questions 1 and 2, was designed to determine whether diazepam treatment of monkeys, at the termination of 6 months of total social isolation, would substantially reverse the negative behavioral effects of isolation. The long-term results of treatment and whether they are maintained through social challenge will be reported in the future.

METHOD

Subjects

Four rhesus macaque monkeys (2 males and 2 females), laboratory born and separated from their mothers at birth, were reared for the first 15 days of their lives in the laboratory nursery using the procedure described by Blomquist and Harlow (8). Each subject was then placed in an individual isolation chamber, as described by Rowland (2), where it remained for 8 months, unable to see or contact any social agent. One female animal died as the result of an overwhelming enteritis that she contracted during the fifth month of isolation.

Procedure

After 7 months of isolation, and while the monkeys were housed in their isolation chambers, drug administration was begun. Each subject was briefly removed from its isolation chamber twice daily at 8 a.m. and 4 p.m. to receive 2 mg/kg of diazepam in suspension by nasogastric entubation. This continued for 4 weeks, at which time each subject was permanently removed from its isolation chamber and placed in a bare 1.90-cm wire mesh cage measuring 76.25×61×76.25 cm (hereafter called the "home cage"), where it could see and hear but not contact the other monkeys. Drug administration continued as described throughout the remainder of the experiment. Four weeks after termination of isolation the subjects were introduced as a group of three to a playroom for twice-daily, 30-minute testing sessions held 4 days a week.

Data Collection

After 6 months of isolation each subject was observed for two 10-minute periods daily (at 10 a.m. and 3 p.m.). Thus there was 1 month of formal observation prior to treatment. Observation continued on this schedule for the remainder of the experiment. The first 2 months of observation were through a one-way mirror in the isolation chamber; the third month was in the home cage; and the fourth through ninth months of observation were through a slanted plastic window in the playroom. The times of the observation were scheduled to follow the morning drug administration by 2 hours and to precede the afternoon drug administration by 1 hour.

During each observation period the behavior of the subjects was scored using each of the 31 behavioral categories defined in appendix 1. Category scores were recorded as modified frequencies, i.e., the number of 15-second intervals in which the behavior occurred during the 10-minute rating period for each animal in each session. Two experienced testers with high interrater reliability recorded the subjects' behavior. Ordering of testing among the subjects was randomly determined.

Data Analysis

For purposes of data analysis the individual behaviors were combined into 7 groupings (see Appendix 1), and combined modified frequencies were calculated for each grouping for each of the following time periods: baseline chamber; drug chamber; drug home cage; drug playroom 1, 2, 3, and 4; and postdrug playroom 1 and 2. Each period represented a time block of 4 weeks.

A Mann-Whitney U test was employed to compare scores from the following time blocks: baseline chamber versus drug chamber; drug chamber versus drug home cage; drug playroom 1 versus drug playroom 2, 3, and 4; and drug playroom 4 versus postdrug playroom 1 and 2. Scores from the morning and afternoon sessions were analyzed separately.

RESULTS

Data analysis yielded the following general findings:

1. Six-month total social isolates can be partially rehabilitated with diazepam.
2. Not all subjects respond.
3. Discontinuation of diazepam results in relapse.

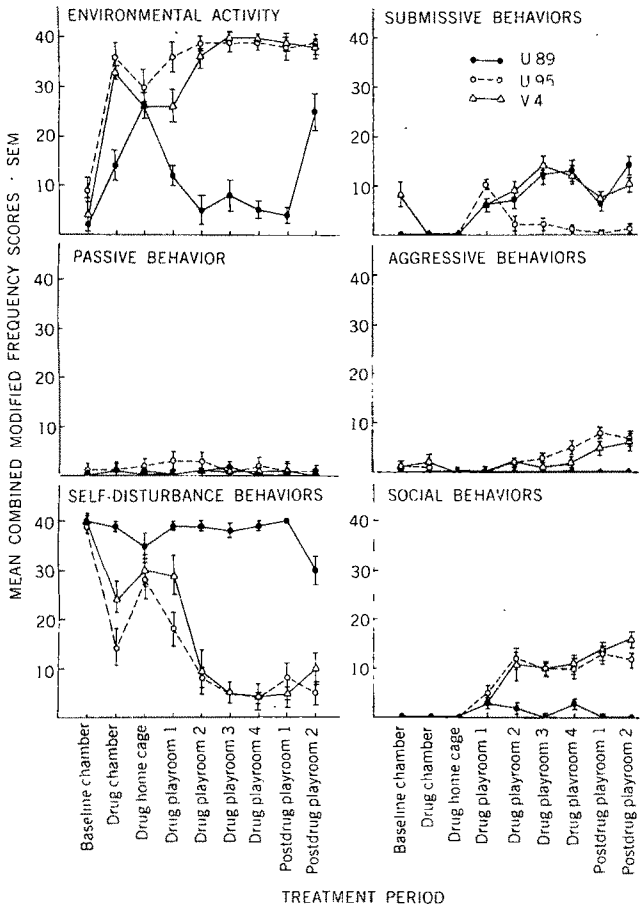

Figure 1 presents the mean combined modified frequency scores (±SEM) for 6 of the collapsed categories for each treatment period. (The data reflect the combined scores of both rates.) Table 1 gives the values obtained in the statistical analysis of the data. The miscellaneous category, which consisted of behaviors that did not clearly fit into any of the other categories, yielded no useful data on analysis and therefore is not included in the discussion that follows.

Response in Isolation Chamber

During this period all 3 animals responded to diazepam with a decrease in self-disturbance behaviors. With 2 of the animals (U 95 and V 4), the response was highly significant in both the morning and afternoon test sessions. The self-disturbance behaviors of the third monkey (U 89) decreased less dramatically, and the decrease was significant only in the afternoon session. All animals demonstrated a highly significant increase in environmental exploration in both test sessions.

Animal V 4 had the highest scores on submissive behaviors during the baseline isolation chamber period, and these declined significantly with diazepam treat-

FIGURE 1
Mean Combined Modified Frequency Scores for Six Categories of Behavior Exhibited by Three Monkeys Treated with Diazepam

ment. This animal also had a slight but significant increase in scores on passive behavior. Although both morning and afternoon scores changed significantly, there was no statistical significance between the two times of day. Because the increase in V 4's passive behavior was not marked and at the same time the increase in environmental behaviors was so dramatic, it seems unlikely that the change in passivity reflected sedation by diazepam.

These data clearly indicate that the behavioral repertoire of isolate-reared monkeys can be significantly altered even within isolation by diazepam treatment.

Response in Home Cage

An interesting difference in the pattern of response of the 3 animals began to manifest itself as they were removed from their isolation chambers and placed in their home cages. The 2 animals with the greatest decrease in self-disturbance behaviors within the chamber (U 95 and V 4) then reversed their responses. They both evidenced a significant increase in self-disturbance behaviors, and U 95 also had a significant decrease in environmental exploration. The remaining animal, U 89, who had shown less of a decline in self-disturbance behaviors in isolation, had a further reduction in these behaviors in the home cage and, at the same time, significantly increased its environmental exploration. These changes, which remained consistent through morning and afternoon observations, demonstrated early differences in response patterns to treatment.

Response in Playroom

There was no appropriate baseline with which to compare the first period of playroom behavior. To use home cage observations as this baseline would have been unfair, since social behaviors that naturally competed with disturbance behaviors could only be scored during playroom observation, and this might have falsely exaggerated a decline in disturbance behavior. Comparisons were therefore made between each subsequent playroom period and the first playroom period. However, there is a large body of literature to document the devastating effects of 6 months of total social isolation on the playroom behavior of rhesus monkeys (e.g., references 2, 3, 9).

The previously noted differences in patterns of response became even more marked as the experiment progressed. U 95 and V 4, whose improvement was greater in the isolation chamber and who showed some reversal in the home cage, demonstrated a highly significant therapeutic response with continuing playroom experience. There was a significant reduction in self-disturbance behaviors in 2 of the animals. Environmental exploration increased to a maximum in a mirror image of the decline in disturbance behaviors, and social responses appeared. With one exception these changes were consistent through morning and afternoon test sessions; that is, the differences in U 95's afternoon environmental explorations in playroom 3 versus playroom 1 were not significant.

The third animal, U 89, whose maximum therapeutic response was in the home cage, completely reversed all positive changes when he was confronted with social experiences. His disturbance behaviors were at a maximum throughout playroom testing, his environmental exploration decreased to very low levels, and there was no appearance of social responses. These observations were consistent through morning and afternoon testing.

Analysis of the change in passive behavior through the playroom periods 1 through 4 showed low levels with no consistent trends in any of the animals. Analysis of the submissive scores revealed the pattern of dominance that emerged among the monkeys.

Isolation animals classically reveal little or no socially appropriate aggressive behaviors. It is interesting to note that the 2 animals who showed positive response to the drug in other categories also had a significant increase in aggressive behaviors, although this increase in V 4 was noted only in the morning test sessions. However, this increase was almost entirely comprised of threats and barks, i.e., facial and vocal expressions, rather than acts of aggression.

*By Mann-Whitney U test.

These data are important in that they clearly demonstrate a therapeutic response to diazepam that included the appearance of social and aggressive behaviors without social models. However, it should be noted that not all monkeys respond and, in those which do, the social and aggressive behaviors are not at the response level of normal monkeys either in quality or quantity.

Response in Postdrug Playroom

Although there were some trends indicating reversal of improvement in U 95 and V 4 during the first 4-week period off diazepam, complete reversal was delayed until weeks 4 through 8.

Some interesting phenomena were noted with nonresponder U 89. After 4 weeks off diazepam, his environmental activity increased significantly, his disturbance behaviors decreased slightly but significantly, the minimal social response disappeared, and submissive responses decreased significantly in the afternoon session.

DISCUSSION

The results of this experiment indicate that the antianxiety agent diazepam will reduce the negative behavioral effects of 6 months of isolation in rhesus monkeys. As in human clinical research, the availability of subjects in primate research is often not ideal, and this

study was limited by the small number of experimental subjects and the unavailability of concurrent control subjects.

Although there were no concurrent controls, there are data available about the fate of 6-month isolates (2, 3, 9). These data indicate that historically there was no spontaneous reversal of disturbance activity or appearance of environmental exploration or social interaction for 4 to 6 months following isolation. When changes did appear, they were not at the level of the changes noted much earlier in this paper. It therefore seems unlikely that the recovery we noted would have been spontaneous. Still, this pilot study should be replicated with a larger number of experimental subjects and with placebo control subjects.

Comparison of the degree of rehabilitation achieved with diazepam versus chlorpromazine (7) shows that earlier treatment with diazepam provides greater rehabilitation. Both drugs will reduce disturbed behaviors, but treatment with diazepam results in higher, more consistent increases in environmental exploration and social and aggressive behaviors. This comparison is limited by the degree to which the populations studied in each experiment differ, i.e., in rearing experience, age of subjects at outset of treatment, and sexual distribution of the animals. Whether the improvement we noted was due to the treatment agent alone must be determined in future studies.

Despite the limitations of this study, it is now clear that chlorpromazine is not the only agent that can effect therapeutic change in isolate monkeys and hence makes it more likely that chlorpromazine's effectiveness is due to its nonspecific rather than its antipsychotic properties. These data argue against the isolation syndrome in monkeys as a model for human psychoses and illustrate the importance of not prematurely attaching clinical labels to the abnormal behavior of animals until comprehensive rehabilitation and mechanism studies are completed. Apparent behavioral similarities will not suffice. Of course, we cannot completely rule out the isolation syndrome as being "psychotic-like." It is theoretically possible that monkeys which are more severely affected by the isolation are "psychotic" and, while unresponsive to antianxiety agents, are responsive to antipsychotic drugs. Further work will be necessary to determine whether this possibility has merit.

The reasons for the monkeys' differential response to diazepam are unclear. Based on the nonresponder's initial improvement in the chamber and in the home cage, we explored the hypothesis that he would respond with higher doses of diazepam. Drug dosage in this subject was gradually increased over a period of 2 months to 9 mg/kg. No side effects were noted, and dosage remained at that level for another month. No further improvement was observed.[1]

The differential response of isolates to rehabilitative attempts has been noted in other studies. In a study by McKinney and associates (7), chlorpromazine was effective in decreasing self-disturbance behaviors in 3 of 4 monkeys. Harlow and Harlow's report (1) of the first 2 animals isolated for 6 months described them after 8 months of postisolation exposure to peers. "One must be characterized as extremely disturbed and almost devoid of social behavior. The other resembles a normal two month old rhesus infant in its play and social behavior, and the indications are that it will never be able to make mature contact with its peers."

Other experimenters who have noted this difference have found it to be sex related. Clark (9) and Mitchell (10) found that males were more difficult to rehabilitate than females. They also noted that males were more severely affected by the early isolation.

The nonresponder in our study was male. Other observations about him support the idea that he was more severely affected by the isolation than were the other 2 animals. Unlike the others, his disturbance behaviors included head banging, convulsive jerks, and spasms. In addition, he was unable to make the transition from a liquid diet to solids until several months after the others, and he seemed more susceptible to injury and illness. While it seems that he was more severely affected and more difficult to rehabilitate, 1 of the responders was male and his improvement paralleled that of the female's. These observations point to the need for future isolation studies to include greater numbers of animals, equal distribution of sexes, and attention to differential symptoms produced by isolation, as well as analysis of differential responsiveness to attempts at rehabilitation.

APPENDIX 1
Classification and Definitions of Behavioral Categories

ENVIRONMENTAL ACTIVITY

Environmental exploration: any tactile or oral exploration of the physical surroundings.

Locomotion: ambulation of one or more full steps.

Self-play: active behavior in which the subject shows no orientation to other animals; involves one or more of running, vigorous bounding, and rebounding off enclosure in a fairly continuous fashion.

PASSIVE BEHAVIORS

Passivity: maintenance of a static position for a minimum of three seconds with no simultaneous behavior.

SELF-DISTURBANCE BEHAVIORS

Huddle: self-enclosed, fetal-like position incorporating any or all patterns of self-clasp, self-embrace, or lowered head.

Rock: repetitive, nonlocomotive forward-and-backward movement.

Self-bite: specific, vigorous self-directed bite.

Self-clasp: firm manual or pedal clutching of self, excluding the genital area.

Self-mouth: oral contact with any part of the body exclusive of the genital area, excluding biting.

Stereotypy: identical movements maintained in a rhythmic and repetitive fashion for at least three cycles (scored independently and excluding locomotion).

SUBMISSIVE BEHAVIORS

Escape: direct oriented running from another animal differentiated from "yield" in that the subject is intensely fleeing to avoid any possible interaction.

Fear grimace: facial expression resembling a smile that is produced by pulling the lips back and exposing the teeth.

Screech: high-intensity vocalization resembling a scream.

Yield: oriented movement or withdrawal by an animal submitting or ceding area to another animal.

AGGRESSIVE BEHAVIORS

Aggression: vigorous and/or prolonged biting, hair-pulling, and clasping accompanied by one or more of threat, barking, piloerection, or strutting.

Attack: noncontact approach or chase accompanied by threats, barking or other indications of hostility.

Bark: low-pitched, staccato-like vocalization that resembles coughs or yips.

Threat: facial expression produced by pulling the ears back and pulling the lower jaw down and out.

SOCIAL BEHAVIORS

Play: oriented rough-and-tumble activity with or without locomotion and/or mutual and nonmutual chase.

Present: tail raised with erect and rigid stance of hind quarters oriented to another animal.

Proximity: maintenance of a distance of three inches or less from another animal for at least three seconds.

Social exploration (active or passive): oral or manual examination of another animal (scored whether the initiator or recipient of such behavior).

Social groom (active or passive): discrete picking or spreading of the fur of an animal (scored for both animals involved).

Social sex: all sexual mounting and thrusting behavior, whether appropriate or inappropriate.

MISCELLANEOUS BEHAVIORS

Contact cling: maintenance of gross body contact with one or more animals.

Convulsive jerk: any spasmatic rigid movement of the body; involuntary jerking of the body.

Coo: drawn-out dove-like cry in a variety of pitches.

Miscellaneous vocalizations

Nonsocial sex: Oral or manual self-manipulation of the genital area.

Self-groom: Discrete self-directed picking and/or spreading of the fur.

Spasm: Single or repetitive sudden convulsive jerk involving a major part of the body.

Importance of Dopamine Metabolism for Clinical Effects and Side Effects of Neuroleptics

BY HERMAN M. VAN PRAAG, M.D., PH.D., AND JAKOB KORF, PH.D.

The authors studied the relation between human central dopamine (DA) metabolism and the clinical effects of neuroleptics. The neuroleptic-induced increase in central DA turnover (an indicator of the degree of DA receptor blocking) was found to be positively correlated with the therapeutic effect of neuroleptics and the development of hypokinetic-rigid symptoms. This supplies a direct argument in support of the contention that DA antagonism is related to the occurrence of clinical effects. The authors also found indications that neuroleptics of different chemical types do not significantly differ in their intrinsic ability to provoke hypokinetic-rigid symptoms, that development of these symptoms depends on the patient's individual susceptibility, and that individual susceptibility is based on relatively low DA turnover.

NEUROLEPTICS of the group of phenothiazines, butyrophenones, and diphenylbutylpiperidines enhance intracerebral dopamine (DA) turnover in test animals (1–3). One hypothesis relates this phenomenon to the blocking of postsynaptic DA receptors by neuroleptics and regards it as a compensatory phenomenon aimed at breaking the block (4–6). It has also been hypothesized that the antipsychotic action of neuroleptics largely depends on receptor blocking in the mesolimbic and mesocortical DA system but that the occurrence of hypokinetic-rigid symptoms depends more on receptor blocking in the nigrostriatal DA system (7–9). This hypothesis is based on two arguments: 1) neuroleptics regarded as extrapyramidally very active in human individuals are believed to cause a more marked increase in nigrostriatal DA turnover than neuroleptics that produce fewer motor side effects; 2) anticholinergic antiparkinson drugs antagonize the extrapyramidal side effects of neuroleptics without affecting their antipsychotic effect. According to Andén and associates (7–9), on the biochemical level anticholinergic antiparkinson drugs reduce the neuroleptic-induced increase in turnover in the nigrostriatal DA system but exert less influence on the increase in turnover in the mesolimbic and mesocortical DA system.

In earlier studies we found suggestive evidence that neuroleptics of the phenothiazine and butyrophenone type produce a dose-dependent increase in central DA turnover in human subjects as well as in animals (10); that the dopaminergic system in psychotic patients can be hyperactive, but this phenomenon is related to motor hyperactivity rather than to the presence of such "genuine" psychotic symptoms as delusions and hallucinations (10); and that the differential influence of neuroleptics on the two DA systems could not be confirmed in rats (11). The DA turnover in the caudate nucleus on the one hand and in the nucleus accumbens and olfactory tubercle on the other showed a virtually parallel (i.e., identical percent) increase in response to a series of disparate neuroleptics.

Furthermore, we found that neuroleptics described by clinicians as causing little extrapyramidal activity do not exert a significantly less marked influence on

The authors are with the Department of Biological Psychiatry, Psychiatric University Clinic, Oostersingel 59, Groningen, The Netherlands, where Dr. van Praag is Professor of Biological Psychiatry and Dr. Korf is Research Biochemist.

striatal homovanillic acid (HVA) than neuroleptics described as frequently provoking extrapyramidal symptoms (11). Wiesel and Sedvall (12) reported similar findings. These data would seem to point to two possible conclusions. 1) Neuroleptic-induced extrapyramidal symptoms and increased DA turnover in the nigrostriatal system (results of receptor blocking) are not correlated in man. This is improbable in view of, for example, what we know of the pathogenesis of Parkinson's disease. 2) The various neuroleptics do not differ substantially in their intrinsic ability to provoke extrapyramidal symptoms in human individuals. This would be at variance with the clinical view that they do.

Investigations into the correlation between neuroleptic activity and DA metabolism were continued in our present study with reference to the following questions:

1. Is there a correlation between the therapeutic and extrapyramidal effects of neuroleptics and their stimulant effect on central DA turnover (viewed as a yardstick of the severity of the transmission inhibition provoked in the dopaminergic system)?
2. Do neuroleptics differ in their ability to provoke extrapyramidal symptoms, more specifically, hypokinetic-rigid symptoms? If, contrary to the clinical view, this would not be demonstrable, this would mean that the occurrence of these symptoms at a given neuroleptic dosage is determined less by the type of neuroleptic used than by the patient's individual sensitivity. In that case the following question arises:
3. Is DA turnover an important factor with regard to this individual sensitivity in that low pretherapeutic DA turnover predisposes an individual to hypokinetic-rigid symptoms?

DA turnover was evaluated on the basis of the probenecid-induced increase in HVA concentration in the lumbar cerebrospinal fluid (CSF); the rationale for this method has been described elsewhere (13–16).

Informed consent was obtained for all human subjects studied.

METHOD

Study 1

Thirty-two patients with acute psychoses admitted to the research unit of our department of biological psychiatry were treated with chlorpromazine (Largactil, N=12), haloperidol (Serenase, N=10), or perphenazine (Trilafon, N=10). At admission all psychotropic medication was discontinued. Neuroleptic medication was started at least 5 and at most 10 days after admission unless the psychosis had faded without medication (this has happened from time to time). In 10 cases agitation made it impossible to refrain from giving medication until neuroleptic medication was started. These 10 patients were sedated in the interim period with a standard powder containing 100 mg of amobarbital (Amytal), 100 mg of bromisovalum (Bromural), and 100 mg of methylphenobarbital (Prominal). At the most, this medication was given 3–4 times daily.

Unless there was severe agitation, the patients were randomly placed in either the chlorpromazine or the perphenazine group 5–10 days after admission. The dosage was kept flexible as follows:

Each patient received 1 capsule 3 times daily. The capsule might contain placebo; 50, 100, 150, or 200 mg of chlorpromazine; or 2, 4, or 8 mg of perphenazine. The patient could thus receive 0–600 mg of chlorpromazine or 0–24 mg of perphenazine daily. The capsules were identical. To ensure optimal therapeutic effect, the dosage was determined daily by a psychiatrist who was not one of the raters. Every day a research assistant supplied the head nurse of the research unit with the capsules, specifying which patient was to receive which capsules.

In the case of severe motor unrest the patient was treated with 6–15 mg of haloperidol; in 5 cases this agent was given intramuscularly during the first 1–3 days of drug administration because oral medication was refused. The haloperidol dosage considered necessary was also determined daily.

The test patients remained in the research program for at least 1 week and at most 3 weeks. The experimental period was 1 week for those who responded inadequately to the medication given and for whom longer postponement of appropriate medication was not considered justifiable.

The patient's mental condition was scored twice weekly on a 10-item, 5-point rating scale by the research nurse and the attending physician, working independently. The highest score on this scale was 40 (maximal pathology), and the lowest was 0. The occurrence of any hypokinetic-rigid and dyskinetic symptoms was assessed twice weekly by the attending physician, who used a 4-point rating scale.

The central DA metabolism of all 32 patients was studied with the aid of the probenecid technique. The first test was carried out before medication was administered, after a period of 5–10 days without neuroleptic medication. The second test was done at the end of the first week of medication administration. The procedure of the probenecid test has been described elsewhere (16). Concentrations determined in the CSF were, in addition to HVA (17), 5-hydroxyindoleacetic acid (5-HIAA) (18) (the principal degradation product of serotonin), and probenecid (19). The treatment of any extrapyramidal pathology was always started after the second probenecid test.

The raters were unaware of the contents of the capsules and the results of the CSF determinations.

In the independent opinions of the attending physician and the supervising psychiatrist, all patients showed delusions and/or hallucinations. An idea that in all probability was inconsistent with reality but was nevertheless insusceptible to correction was considered a delusion. An experience was regarded as a hallucination if 1) in the patient's own words it occurred in a sensory modality (auditory, visual, gustatory, olfac-

tory, tactile, kinesthetic, or combinations of these), and 2) in the interviewer's opinion current objective stimuli were either totally absent or grossly inadequate to account for the experience (20). Patients suffering from melancholia (deep endogenous depression with delusions of guilt and/or poverty) were excluded from this study.

The group studied consisted of 19 women and 13 men. The average age of the women was 36 (range, 20–58), and that of the men was 40 (range, 19–65). Table 1 presents a general view of the predominant symptoms of these patients and the etiological factors to which the greatest importance was attached in a given case. The hospitalizations of 9 women and 5 men were due to relapses; 4 women and 4 men had a history of three or more previous hospitalizations for psychosis.

Study 2

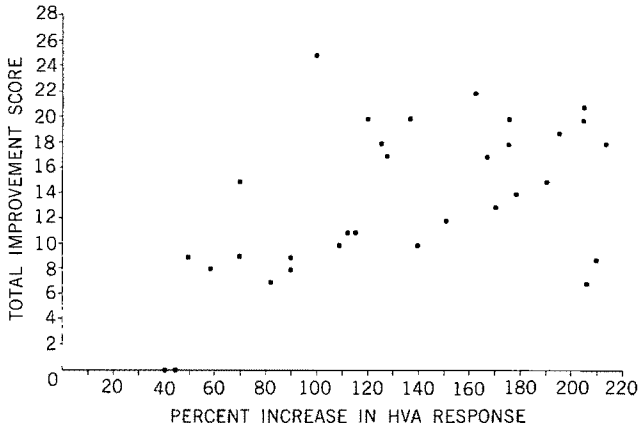
Forty patients per medication group were chosen at random from all patients seen by one of us (H.M.v.P.) for whom chlorpromazine, fluphenazine (Moditen), perphenazine, haloperidol, or chlorprothixene (Truxal) had been prescribed because of psychosis sometime during the years 1958–1975. These groups of 40 patients each were arbitrarily subdivided into high-dose and low-dose groups. Table 2 indicates which doses were considered low and which high. An effort was made to establish how many of the patients had been given an antiparkinson drug because of hypokinetic-rigid symptoms during the first month of medication. These patients were either treated or had their treatment supervised by one of us (H.M.v.P.). The age distribution in the 5 groups did not significantly differ.

Study 3

We also studied 43 patients treated for psychotic syndromes with 150–600 mg of chlorpromazine a day or with 3–15 mg of haloperidol a day (including 22 of the 32 patients in study 1) to establish whether a correlation existed between the CSF HVA response to probenecid before medication and the occurrence or nonoccurrence of hypokinetic-rigid symptoms during the first 3 weeks of medication administration. The motor symptoms were scored as described for study 1, and any necessity of antiparkinson drugs was also noted. Our policy is to prescribe these agents even for mild extrapyramidal disturbances if the patient complains about them. We do not give them prophylactically.

Statistical comparisons for studies 1, 2, and 3 were made using Student's t test for grouped or paired data (one tailed) and Bravais-Pearson correlation coefficients.

RESULTS



Study 1

Figure 1 shows the relation between the percentual increase of the HVA response to probenecid caused

Increase in HVA Response to Probenecid and Hypokinetic-Rigid Symptoms in 32 Patients During Neuroleptic Administration

by 1 week's medication with one of the three neuroleptics used and the improvement scores at the end of the first week of medication. The improvement score indicates the difference between the pretherapeutic total score and the mean of the total scores at the end of the first week of medication. The relation is statistically significant ($p<.03$). The same applies when we plot the summated scores for the three prototypically psychotic items, delusions, hallucinations, and anxiety (see figure 2; $p<.05$).

Figure 3 indicates the mean increase of HVA response to probenecid during neuroleptic medication in relation to pretherapeutic levels in the group of patients without, the group with mild, the group with moderate, and the group with severe hypokinetic-rigid symptoms. In patients with hypokinetic rigidity the HVA response showed a more marked increase than in those without motor side effects ($p<.05$).

The 5-HIAA accumulation in response to probenecid (a measure of serotonin turnover in the CNS) was not influenced by the neuroleptics used; this corroborates previous findings (10). The probenecid concentration in the CSF varied within normal limits (11.33 ± 4.95 μg/ml). The percentual increase in HVA accumulation did not correlate with the CSF probenecid concentration before or during medication. The average daily dose was 425 mg of chlorpromazine, 10 mg of haloperidol, and 20 mg of perphenazine.

Study 2

The retrospective study of patients who had been treated with neuroleptics of various types showed that the number of patients who required antiparkinson drugs during the first month of medication was larger among those given a high than among those given a low dose (see table 2). Within the low- and high-dose groups, however, the indication was established with virtually the same frequency whether the patient was treated with a phenothiazine derivative of the dimethyl series, one of the piperazine series, a butyrophenone, or a thioxanthene derivative.

Study 3

The correlation between pretherapeutic HVA response and the development of neuroleptic parkinsonism was investigated in 43 patients. Of the 23 patients given chlorpromazine, 8 were given a low dose and 15 received a high dose (see table 2 for definition of high and low doses). Two patients in the low-dose chlorpromazine group required antiparkinson medication for hypokinetic-rigid symptoms during the first 3 weeks of medication; 4 patients in the high-dose chlorpromazine group required this medication. In both groups the pretherapeutic HVA response was lower in

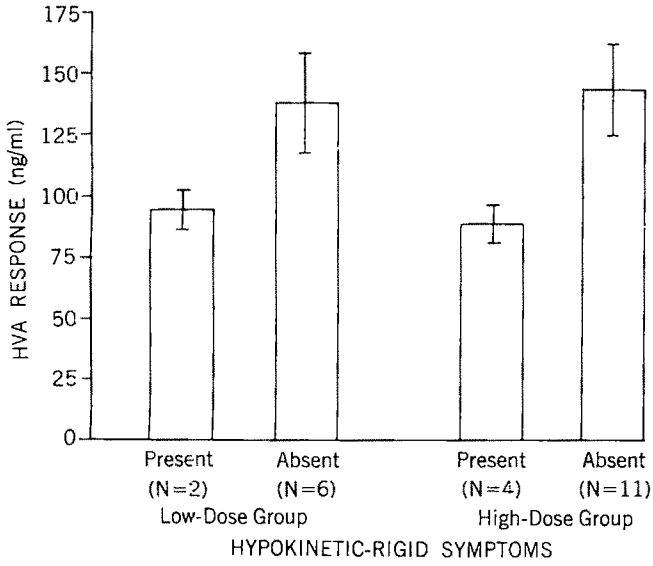
HVA Response to Probenecid Before Administration of Low or High Doses of Chlorpromazine and Hypokinetic-Rigid Symptoms in 23 Patients During First 3 Weeks of Drug Administration



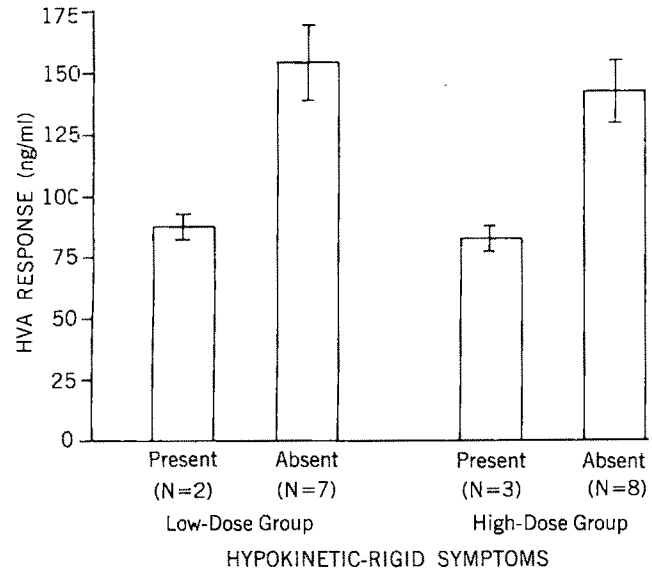


FIGURE 5
HVA Response to Probenecid Before Administration of High or Low Doses of Haloperidol and Hypokinetic-Rigid Symptoms in 20 Patients During First 3 Weeks of Drug Administration

patients with than in those without hypokinetic-rigid symptoms. The difference was not significant (see figure 4).

Of the 20 patients treated with haloperidol, 9 were given a low dose and 11 received a high dose. Two patients in the low-dose haloperidol group and 3 in the high-dose haloperidol group developed hypokinetic-rigid symptoms of such severity that antiparkinson medication was considered necessary. In the low-dose as well as in the high-dose group the HVA response was less marked in patients with than in those without hypokinetic-rigid symptoms. The difference was not significant (see figure 5).

Comparison of the 11 patients who developed hypokinetic-rigid symptoms during neuroleptic medication with the 32 patients who did not showed that the HVA response in the former group was significantly less marked than that in the latter ($p<.05$).

We divided the patients into low-dose and high-dose groups in order to eliminate the coincidence that low HVA responders were given mostly large doses of neuroleptics and thus ran an increased risk of extrapyramidal side effects. In that case the correlation between HVA response and motor symptoms would have been spurious.

The pretherapeutic 5-HIAA accumulation in response to probenecid did not correlate with occurrence or nonoccurrence of hypokinetic-rigid symptoms. Moreover, the two groups did not differ significantly in CSF probenecid concentration.

DISCUSSION

Neuroleptics of different chemical types increase the central DA turnover in test animals—a phenomenon that is probably secondary to a blocking of postsynaptic DA receptors. Insofar as the probenecid-induced accumulation of HVA in the lumbar CSF is an indicator of the DA turnover in the CNS (as we assume it to be), this is also the case in human individuals (10, 21–23). The present study found a positive correlation between the degree of increase in DA turnover caused by a neuroleptic in man and the neuroleptic's therapeutic effect. A comparable relation was demonstrated between DA turnover and the development of hypokinetic-rigid symptoms. This supplies a strong, direct argument for the contention that changes in DA metabolism are related to the occurrence of the clinical effects of neuroleptics. Human studies had previously yielded only one indirect argument in support of this view, i.e, the observation of Carlsson and associates (24) that the therapeutic effect of neuroleptics is potentiated by α-methyl-*p*-tyrosine (AMPT), which is an inhibitor of tyrosine hydroxylase and therefore of DA and noradrenaline (NA) synthesis.

Of course, this does not imply that the clinical action profile of neuroleptics is determined exclusively by changes in DA metabolism. Neuroleptics also influence the NA and acetylcholine metabolism, for example, but the clinical importance of this influence is unknown. In clinical experiments we observed no influence of chlorpromazine on the concentration in the CSF of 3-methoxy-4-hydroxyphenylglycol (MHPG), the principal central NA metabolite (10). However, we measured basal concentrations because MHPG transport is not probenecid sensitive; basal concentrations of monoamine (MA) metabolites in the CSF are a less sensitive indicator of MA turnover than the values af-

ter probenecid loading (25). It is currently not possible to obtain information on the human central acetylcholine metabolism; it is uncertain whether the choline concentration in the CSF is indicative of this (26).

The human nigrostriatal and mesolimbic DA systems cannot be separately assessed. Consequently, we do not know whether certain clinical effects of neuroleptics correlate with an influence on a given DA system. In the study of current neuroleptics this seems to present no serious disadvantage because, unlike Andén and associates (8, 9), we found their influence on both DA systems always to be parallel. A small increase in DA turnover in the one system is associated with only a small increase in the other, and vice versa (11). Furthermore, neuroleptics described by clinicians as causing little extrapyramidal activity do not exert a significantly less marked influence on transmission in nigrostriatal DA neurons than neuroleptics described as frequently provoking extrapyramidal symptoms (11).

On the basis of the available knowledge about the pathogenesis of Parkinson's disease, we considered it unlikely that the motor side effects of neuroleptics and blocking of DA receptors in the nigrostriatal system could be unrelated. The lack of correlation between DA effects and extrapyramidal effects of neuroleptics could be explained by differences in their anticholinergic potency, as described by Snyder and associates (27). The stronger their anticholinergic activity, the fewer side effects they would induce.

We studied another possible explanation: the clinical view that neuroleptics differ widely in their ability to provoke extrapyramidal symptoms might be biased. We found indications to this effect as far as hypokinetic-rigid symptoms are concerned. We have no similar data on hyperkinetic or dyskinetic side effects. In our retrospective study of five neuroleptics (three of the phenothiazines, one butyrophenone, and one thioxanthene derivative) (study 2) we established that the incidence of parkinsonian symptoms was lower at lower doses than at higher doses but that within a dose range (low or high) the incidence was virtually the same with the various neuroleptics. This raised the suspicion that occurrence of parkinsonian symptoms in response to a given dose of a certain neuroleptic is determined less by the intrinsic property of the drug than by the patient's individual susceptibility. This hypothesis was confirmed in that we demonstrated for two neuroleptics (chlorpromazine and haloperidol) (study 3) that within a certain dose range the HVA response to probenecid before medication administration was lower in patients who would than in those who would not develop hypokinetic-rigid symptoms.

Therefore, it seems that patients with a lower central DA turnover run an increased risk of developing hypokinetic-rigid symptoms when they are given neuroleptic medication. Should this suspicion be confirmed in a prospective study, the probenecid technique could be used to establish whether prophylactic antiparkinson medication is or is not indicated.

The degree of increase in HVA response caused by neuroleptic medication was positively correlated with the severity of extrapyramidal side effects as well as with the intensity of the antipsychotic effect. However, the conclusion that neuroleptics should be given in large doses until extrapyramidal symptoms are evident would be a hasty one. We are accustomed to considerable prudence in prescribing doses of neuroleptics. It is quite possible that with larger doses than those we give the correlation between HVA response and extrapyramidal symptoms would persist but the correlation between HVA response and therapeutic effect would be lost. Partly also in view of possible permanent damage to the extrapyramidal system, our findings do not tempt us for the time being to accept a more drastic dosage scheme (28).

A Dopaminergic Mechanism in Mania

BY ROBERT H. GERNER, M.D., ROBERT M. POST, M.D., AND WILLIAM E. BUNNEY, JR., M.D.

The authors present a case study that explores the relationship of dopamine function and manic illness through the use of two drugs with relatively specific effects in stimulating and blocking dopamine receptors—piribedil (ET-495) and pimozide, respectively. Piribedil, as well as d*-amphetamine, was associated with manic episodes, while pimozide had an antimanic effect. These observations suggest that dopaminergic mechanisms may be involved in the mediation of manic episodes in at least some patients.*

A RELATIONSHIP of mania and depression to the central catecholamines dopamine and norepinephrine has been postulated by a number of authors (1–6). Their hypothesis states that depression is related to decreased functional catecholamines at critical synapses and that mania is related to an excess. However, neither the hypothesis nor the pharmacological agents upon which the hypothesis has been based clearly differentiate the relative roles for dopamine compared with norepinephrine.

This report describes a treatment program in which two compounds, piribedil and pimozide, enabled us to dissect a dopaminergic component of mood fluctuations in one patient. Piribedil (ET-495) acts primarily by directly stimulating dopamine receptors (7, 8). Pimozide, an antipsychotic agent, blocks dopamine receptors and does so relatively more specifically than other neuroleptics (9), although its effect on noradrenergic mechanisms is still being investigated (10, 11). In addition the patient received *d*-amphetamine, which increases functional catecholamine at the synapse by increasing release and blocking reuptake of dopamine as well as norepinephrine (12–14).

At the time this work was done, the authors were with the Adult Psychiatry Branch, National Institute of Mental Health, Bethesda, Md., where Dr. Gerner was Clinical Associate, Section on Psychobiology, Dr. Post is Chief, 3-West Clinical Research Unit, Section on Psychobiology, and Dr. Bunney is Chief, Adult Psychiatry Branch. METHOD

Subject

The patient was a 47-year-old man whose family history revealed possible bipolar affective illness in three deceased second-degree maternal relatives. The patient's physical and psychosocial development was

unremarkable until he was 24, at which time he began to have severe depressions lasting approximately 6 to 12 months every 2 to 3 years. The patient and his relatives reported manic episodes lasting about 2 weeks and occurring less than 3 times a year. These episodes of mania and depression and those observed in the hospital met the research diagnostic criteria of Spitzer and associates (15) for primary affective disorder.

One year before his admission the patient had received a trial of lithium carbonate but did not take it reliably. For 18 months before his admission he had experienced manic episodes lasting 2 to 5 days once every 2 to 3 months. At the time of admission he had been continuously depressed for 3 months.

The results of a physical examination were within normal limits, and laboratory tests (including T_3, T_4, EKG, EEG, and brain scan) were normal.

Procedure

The patient was hospitalized on a 10-bed research unit at the National Institutes of Health. During the first 5 weeks of hospitalization his depression remained stable and unresponsive to individual and group psychotherapy. Informed consent was obtained after the nature of all medications and procedures was explained. All medication was given on a double-blind basis. Two intravenous infusions of *d*-amphetamine (15 and 20 mg/day, each administered over one minute) were given during the depressive episode in order to study mood elevation response to amphetamine and its possible value in predicting subsequent response to tricyclic antidepressant treatment (16–18). Piribedil was given in slowly increasing doses up to 200 mg/day as part of an antidepressant trial. Pimozide was given in doses up to 14 mg/day.

In order to further clarify alterations in the metabolism of the dopamine, norepinephrine, and serotonergic systems, lumbar punctures were performed to measure the respective metabolites of these systems—HVA (homovanillic acid), MHPG (3-methoxy-4-hydroxyphenyl glycol), and 5-HIAA (5-hydroxyindoleacetic acid). These were performed at 3 p.m., after restricted activity, in a drug-free state during episodes of depression and mania, as previously described (19).

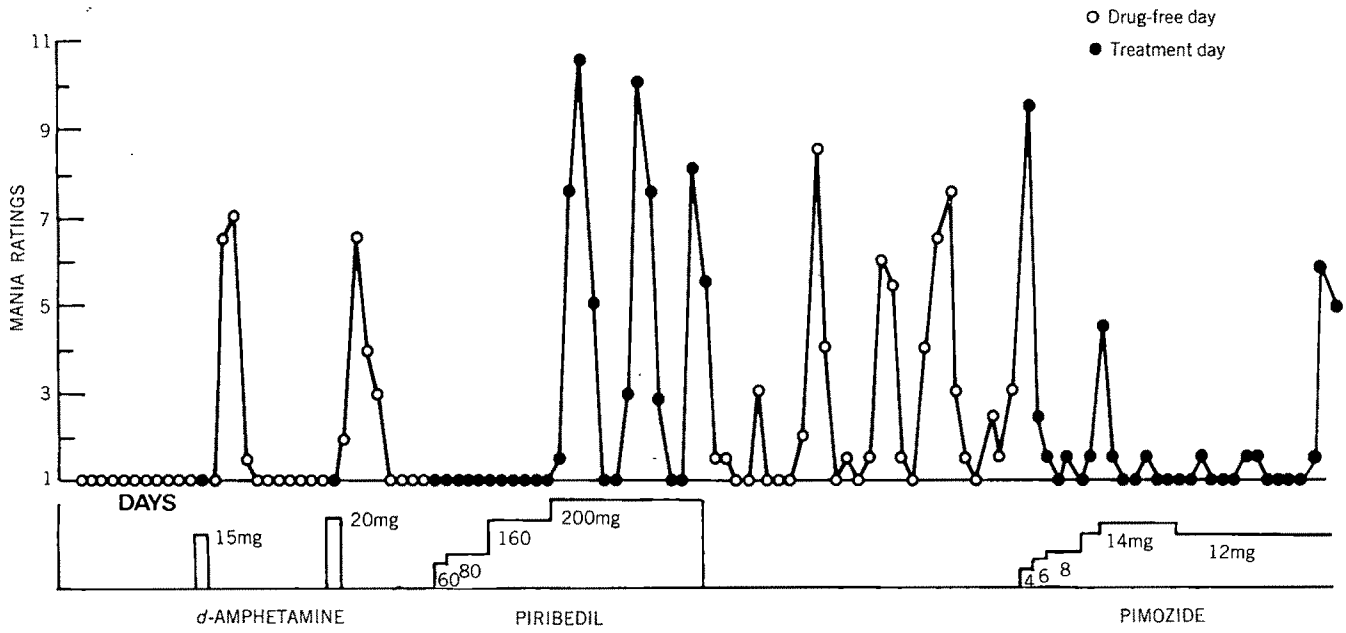
Daily ratings of behavior and mood were made by experienced members of the nursing staff using the global Individual Mood and Behavior Check List (20) and the detailed Manic-State Rating Scale (21).

RESULTS

On the 37th day of hospitalization the patient received 15 mg of *d*-amphetamine intravenously. (Figure 1 shows the patient's responses to each of the drugs given.) He showed no antidepressant response on the day of amphetamine infusion, but on the 38th day he was insomnic, and 34 hours following the infusion he abruptly became manic. For 3 days he displayed symptoms that were classic and typical for him, including hyperactivity, hypertalkativeness, insomnia, intrusiveness, and lability of affect. He returned to his previous level of depression on the 42nd hospital day. Seven days later he received another *d*-amphetamine infusion (20 mg). The next day, 32 hours after the infusion, he again became manic, and this episode lasted 4 days.

After the patient started treatment with piribedil, his depression improved slightly but he still remained symptomatic. On the 12th day of treatment, the day after an increase in the dosage of piribedil, he became manic and displayed the same symptom constellation that he had shown previously. The episode terminated abruptly in 4 days and was followed by 2 nonmanic days, another 4 days of mania, and then 2 more nonmanic days. Piribedil was withdrawn when it became apparent that he was again entering a manic period. The patient continued to exhibit brief manias alternating in a regular fashion with 1 to 3 days of depression (average cycle length=5.5 days). His mood swings clearly had changed, becoming more frequent and more regular than at any previous time.

Treatment with the neuroleptic pimozide reduced the magnitude of the cycles, although mild mood changes continued to be detectable. In contrast to his behavior during manic episodes, the patient began sleeping every night, was able to retain all of his ward privileges, and was able to function well on his hospital job. This treatment with a relatively specific dopamine receptor blocker resulted in a marked diminution of his manic symptoms for about 4 weeks; during the 5th week a full-blown manic episode occurred in spite of continued treatment with pimozide.



The patient then showed a partial response to lithium treatment, continuing to cycle less intensively and less frequently from hypomania to moderate depression. After the phenothiazine trifluoperazine (20 mg/day) was added to the lithium regime, and after several months of intensive milieu and psychotherapeutic work, the patient's mood swings ceased to enter the pathological range and he was discharged.

DISCUSSION

For this patient there appears to be a relationship between increased dopaminergic function and the occurrence of manic episodes and decreased dopaminergic function and the suppression of mania. Following two amphetamine infusions the patient became manic; during treatment with a relatively specific dopamine receptor stimulator, piribedil, he started having regular recurrent manic episodes that persisted following discontinuation of the drug. The manias were successfully treated with a relatively specific dopamine receptor blocking compound, pimozide. Thus all four separate pharmacological interventions illustrated in figure 1 were consistent with dopaminergic involvement in the manic episodes of this patient.

It is noteworthy that a lag of 32 to 34 hours occurred

FIGURE 1
Relationship of Mania to Dopamine Agonists and an Antagonist in One Patient

between the amphetamine infusions and the onset of manic episodes; this time factor may be important to understanding the biochemical processes involved in the triggering of mania. While there is considerable evidence for the role of dopamine in this patient's mania, it should be clarified that neither amphetamine nor piribedil is typically provocative of mania even in bipolar patients; of 20 patients given one or both compounds at the National Institute of Mental Health, this was the only patient who became manic (22, 23).

In addition to the effects on the patient's mania of drugs with relatively specific action on dopaminergic function, the cerebrospinal fluid (CSF) amine metabolite data for this patient support the role of dopaminergic systems in his manic episodes. The patient's HVA level during mania was 43 ng/ml, compared with 3 ng/ml during depression. MHPG levels were, atypically, lower during mania (5 ng/ml) than during depression (23 ng/ml). The 5-HIAA levels did not change (45 ng/ml, 44 ng/ml).

Support for a dopaminergic role in mania is found in other pharmacological and CSF studies. L-Dihydroxyphenylalanine (L-dopa), which affects the synthesis and turnover of dopamine more than that of norepinephrine, has precipitated hypomania in some but not all depressed patients (24–27). Fusaric acid, which decreases norepinephine synthesis by inhibiting dopamine β-hydroxylase, shows little or no alleviation of mania (28) while α-methyl-p-tyrosine (AMPT), which decreases the synthesis of both dopamine and norepinephine, has some antimanic effect (29). The efficacy of the phenothiazines and butyrophenones in mania (30) also suggests the importance of the dopaminergic system (31). The majority of investigators have found the baseline level of the dopamine metabolite HVA in CSF to be higher in mania than in depression, although not higher than in control groups (6). However, motor activity may also be an important factor in these relative increases in baselines levels of HVA during mania (32). In contrast, probenecid-induced accumulations of HVA may be low in both mania and depression (6).

While evidence for alterations in norepinephrine, serotonin, and other transmitters has also been reported in patients with manic illness, the purpose of this case report and brief review has been to highlight the possible involvement of a dopaminergic component in the onset of mania in at least some patients. Although all patients do not react to increases in dopamine function with manic episodes, a subgroup of patients with an increased susceptibility may ultimately be demonstrable using brief clinical pharmacological trials or assessment of amine metabolites in biological fluids. The use of relatively specific pharmacological treatment strategies appears to demonstrate an important role for dopamine in the manic episodes of the patient studied.

Negative Effects of Melatonin on Depression

BY JOHN S. CARMAN, M.D., ROBERT M. POST, M.D., RICHARD BUSWELL, M.D., AND FREDERICK K. GOODWIN, M.D.

In order to test the efficacy of the pineal neurohumor melatonin on depression, the hormone was administered in varying doses to six moderately to severely depressed patients and two patients with Huntington's chorea in a double-blind crossover study. Melatonin exacerbated symptoms of dysphoria in these patients, as well as causing a loss of sleep and weight and a drop in oral temperature. Melatonin increased cerebrospinal fluid 5-hydroxyindoleacetic acid and calcium in three of four patients studied. The authors discuss the implications of this finding.

PREVIOUS REPORTS (1–3) of mood improvement in parkinsonian patients and normal human subjects receiving the pineal neurohumor melatonin prompted our group to undertake a therapeutic trial of melatonin in depression. (Table 1 reviews studies reporting the psychological effects of melatonin.) Melatonin has been shown to increase brain serotonin in animals (11, 12) and urinary 5-hydroxyindoleacetic acid (5-HIAA) in parkinsonian patients (9) and to induce and prolong sleep in human subjects (1, 3, 7–9) and animals (13–15). These properties of melatonin led to our interest in this neurohumor as a possible therapeutic agent in depression, since sleep is frequently reduced in depressive illness and brain serotonin has been hypothesized to be decreased in some forms of depression.

Further rationale for such a trial came from observations that melanocyte-stimulating hormone (MSH), an antagonist of melatonin (7), produces in animals an exaggerated response to noxious stimuli (16, 17). Conversely, a double-blind study reported low-dose oral melanocyte-stimulating-hormone-release-inhibiting-factor (MIF) a more effective antidepressant than placebo in four of five patients (18).

METHOD

Six patients with major primary depressive illness, defined according to the criteria of Spitzer and associates (19), and two patients with Huntington's chorea were hospitalized on research wards at the National Institute of Mental Health. Informed consent was obtained after the nature of the treatment and procedures was fully explained. The patients received varying amounts of melatonin either orally, divided into four equal doses daily, or by intravenous infusion once or twice daily for varying periods of time. The course of active oral melatonin was preceded and followed, for at least one week, by administration of placebo capsules identical in appearance, in a double-blind crossover design. Similarly, intravenous infusions of the active hormone were randomized with placebo infusions on a double-blind basis.

Behavioral ratings were obtained twice daily by consensus of a trained nursing research team (who were blind to all medications) using a modification of the Bunney-Hamburg Mood and Behavior Rating Scale (20), including ratings, on a 15-point scale, of such global items as depression, mania, psychosis, anxiety, and anger (21). The mean values for each item during the 7 days immediately preceding administration of melatonin, the variable number of days at the peak dose, and the placebo week following discontinuation of melatonin were employed in assessing the significance of drug-associated changes by analysis of variance.

An estimate of each patient's total nighttime sleep was determined by nurses making 30-minute checks between midnight and 8 a.m., and oral temperature by electronic thermometer and fasting weight were measured daily at 8 a.m. Blood samples were drawn twice weekly at 8:30 a.m. to monitor endocrine, metabolic, renal, hepatic, and hematologic status. Before melatonin administration and at peak dose, lumbar punctures were performed, in three patients at 9 a.m. without probenecid, and in patient 2 at 3 p.m. following oral administration of probenecid (100 mg/kg) (22) and 15 hours of bed rest.

Cerebrospinal fluid (CSF) 5-HIAA was measured by spectrofluorometric techniques as previously described (22). CSF and serum total calcium and magnesium were measured by atomic absorption spectrometry (23).

TABLE 1
Psychological Effects of Melatonin: A Review of the Literature

Study*	Number of Subjects	Type of Subjects	Length of Study (days)	Peak Daily Dose (mg)	Method of Administration	Psychological Effects
Lerner and Case (4)	2	Normal subjects	1	200	Intravenous	Mild sedation
Norlund and Lerner (5)	6	Normal subjects	28	1000	Oral	Sedation

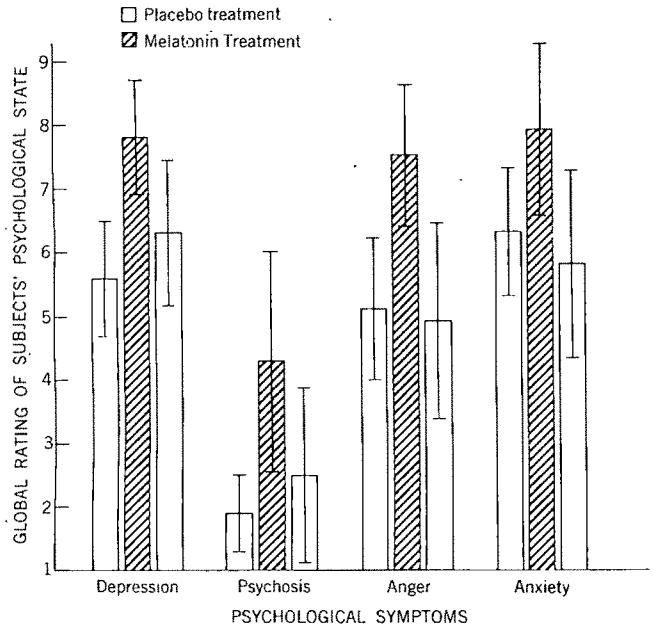
RESULTS

Figure 1 shows the effect of melatonin on the psychological state of the eight patients. Not only was melatonin, by either method of administration, ineffective as an antidepressant, but in every patient it caused some exacerbation of dysphoric mood. Ratings of depression and anger increased significantly for the group as a whole ($p<.01$), while psychosis emerged de novo or worsened in four patients. Anxiety increased as well, although not significantly ($p<.10$).



Two cardinal elements of the vegetative dysfunction characterizing endogenous depression—loss of sleep and weight—seemed specifically worsened during melatonin treatment (see table 2). Nurses' checks, although such crude estimates must be interpreted with caution (24), suggest a drop in nighttime sleep averaging 2.0 hours ($p<.01$), and the magnitude of sleep loss seemed related to the peak worsening of depression in each patient. Patients on melatonin also had an average weight loss of 1.8 kg ($p<.01$). In addition, oral temperature measured at 8 a.m. decreased by an average of 0.8C ($p<.01$) (table 2).

CSF 5-HIAA as well as CSF calcium increased markedly in three of four patients tested (table 3). The sole exception, patient 3, was also the only patient whose depression ratings did not increase on melatonin.

CASE REPORTS

Case 1. This 66-year-old woman had an 18-year history of episodic severe unipolar depression marked by prominent anorexia, social withdrawal, psychomotor retardation, and marked morning awakening. Each of her 12 prior episodes had necessitated hospitalization and parenteral feedings and, despite numerous trials of antidepressant medication, had finally responded only to ECT. During her 24-day trial of oral melatonin (peak dose=1100 mg/day), she developed a clear and dramatically dose-related exacerbation. Figure 2 demonstrates graphically the high correlation of nurses' ratings of psychological state with the dosage of melatonin this patient

FIGURE 1
Effect of Melatonin on Subjects' Psychological State (N=8)*

*Significant differences ($p < .01$, by analysis of variance) were found for the ratings of depression and anger when melatonin treatment was compared with preceding and following placebo treatment.

received. The patient's extreme withdrawal progressed to total mutism, anorexia, rigid immobility, enuresis, and encopresis. Furiously negativistic, she closed her eyes and exhibited alarm when the staff attempted to assist her in eating, grooming, or locomotion. On melatonin the usual lessening of this patient's depressive stupor during the evening disappeared. The exacerbation in her illness lessened slowly during the week following abrupt substitution of placebo.

Case 2. This patient was a 40-year-old woman with a 6-year history of alternate episodes of mania and depression, each requiring hospitalization; her index admission was for a moderately severe retarded depression that was worse during the evenings. During her first week on oral melatonin she developed an extreme lability of mood with sudden unprovoked outbursts of tears, rage, or terror. At peak dose (1600 mg/day) she developed looseness of associations, idiosyncratic expression, bizarre and inappropriate dress and demeanor, ideas of influence and reference, and the appearance for the first time of self-accusatory auditory hallucinations, blocking, and episodes of waxy flexibility several minutes in duration. An abrupt remission of all psychotic symptoms, coupled with a considerable lessening of depression, occurred one day after substitution of placebo following a 16-day trial of melatonin. She subsequently showed further improvement in her depression during lithium carbonate administration.

Case 3. This 44-year-old man had a 10-year history of retarded bipolar depression with episodic alcoholism. While on oral melatonin at a peak dose of 1200 mg/day, no affective worsening was reflected in his global depression ratings, but this patient did report increased sadness, difficulty concentrating, early morning insomnia (although nurses' sleep checks do not reflect this), and daytime drowsiness. He became more withdrawn, developed a prominent anorexia, and for the first time in 4 years of effortless abstinence expressed a desire for alcohol. These symptoms improved a few days after he completed a 9-day trial of melatonin. Later, this patient did not show a clear response to lithium, but he did improve following administration of tricyclic antidepressants.

Case 4. This patient was a 31-year-old woman with a 3-year history of mild to moderate unipolar depression. Although early in her hospitalization she suffered from mild insomnia, anorexia, and agitation, her depression responded well to hospitalization and psychotherapy without antidepressant medication, and she was substantially improved at

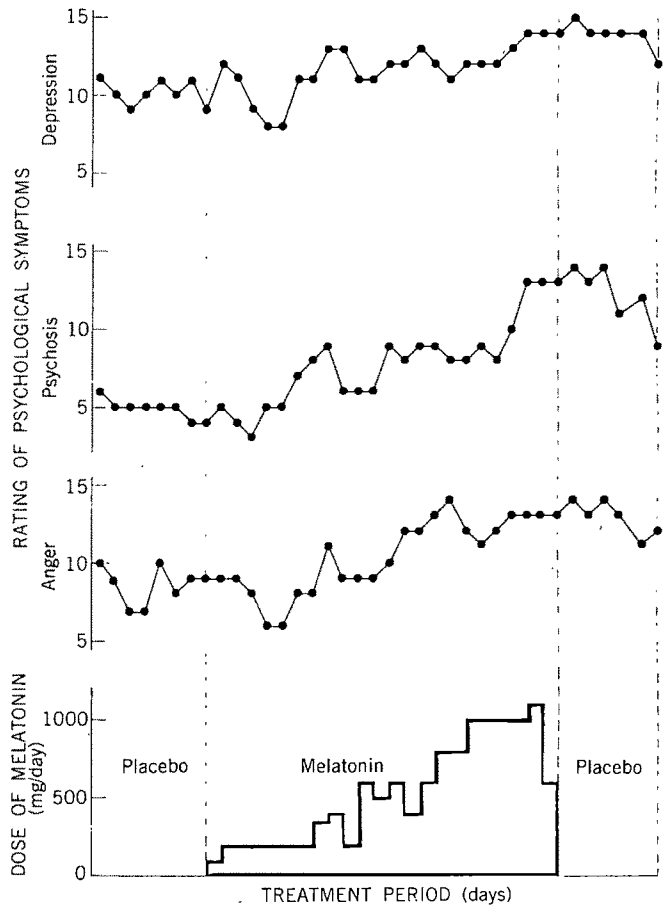
the time her brief trial (3 days) of oral melatonin was begun. She became increasingly tearful and drowsy on melatonin and was felt by the staff to be subtly more distant and withdrawn. She complained of easier fatigability, decreased interests and appetite, and marked morning insomnia at the peak dose of 1200 mg/day.

Case 5. This patient, a 48-year-old woman with a moderate unipolar depression who received intravenous melatonin for 7 days (peak dose=250 mg/day), experienced disturbed sleep, gloominess, argumentativeness, feelings of unreality, and increased tearfulness and reported subjective increases in depression while on melatonin.



Case 6. This 47-year-old man with a moderately severe retarded bipolar depression received intravenously for 3 days the least melatonin given in this study (peak dose=150 mg/day) and showed little behavioral change other than an episode of breakthrough crying within an hour after the infusion of his highest dose. This was the only such crying in his entire hospitalization.

Cases 7 and 8. A 53-year-old woman and a 39-year-old woman had Huntington's chorea with moderate to severe motor dysfunction but only mild mental impairment. Although both were euthymic and without psychotic symptoms before the drug trial, both showed depression and psychomotor retardation during melatonin (peak dose=1200 mg/day) but no alteration in cognitive function and no emergence of psychosis. Patient 7 received melatonin for 12 days, patient 8 for 9 days.

DISCUSSION

The increased dysphoria that we observed in this small number of depressed and choreic patients was associated with sad or hopeless facial and verbal expressions and appeared to be a clear exacerbation of depression and not mere nonspecific sedation, as had been frequently reported in previous trials with human subjects (see table 1). The study was discontinued because of the evidence that melatonin was making this population of patients worse. These findings stand in striking contrast to the "elation" (1), "contentment" (2), and "increased emotional stability" (3)

FIGURE 2
Effect of Melatonin on Psychological State of Patient 1*

*During the period of active drug administration, the correlations between total daily dose of melatonin and ratings of specific psychological symptoms of patient 1 were .54 for anger, .70 for psychosis, and .57 for depression.

reported for other neurologically disordered patients and normal control subjects. Different experimental settings, closer attention to psychological effects, double-blind methodology, and the use of subjects with preexisting psychiatric morbidity or biological vulnerability could have contributed to our discrepant findings. Of possible relevance to our clinical observations are the reports that melatonin reduces spontaneous or appetitive activity in animals at doses even lower by weight than those we employed (16, 25–31).

Our results are consistent with those of Altschule (6), who noted florid exacerbation of schizophrenic symptoms following administration of intravenous melatonin to two previously recovered schizophrenic patients. The development of psychotic symptoms we saw during melatonin administration in the four most severely depressed patients is noteworthy since a variety of psychotomimetic and stimulant agents increase melatonin synthesis (dimethyltryptamine, bufotenine, mescaline, LSD, dimethoxyphenylethylamine [32], amphetamine [33], cocaine [34], and L-dopa [35]), while the neuroleptics diminish it (36)

and augment release of MSH from the pituitary (37).

It has been postulated (38–43) that endogenous or exogenous melatonin might undergo cyclic dehydration to form carbolines with either reserpine-like depressant or psychotomimetic properties. More rapid accumulation of melatonin or such metabolites or greater sensitivity to them might explain the dramatically different behavioral effects of melatonin in psychiatric patients than in normal subjects (44, 45).

Doses of exogenous melatonin administered four times a day might effectively have obfuscated the normal nocturnal, pulsatile synthesis and release of endogenous melatonin (46–49) as well as circadian variations in any behavioral characteristics referable to it. Consequently it is particularly interesting that the previously distinct diurnal differences in symptom severity of patients 1 and 2 became indiscernible at the peak dose of the hormone. If exogenous melatonin were in fact altering critical circadian rhythms, this would provide another explanation of the different effect of melatonin on normal control subjects than on psychiatric patients, who may have abnormal circadian rhythms initially (50–52). We (53) and others (54) have observed a marked, usually transient antidepressant effect of one night's sleep deprivation in severely depressed patients but not in less depressed patients or control subjects. It is an intriguing possibility that elimination of a sleep- or dark-related increase in melatonin might account for the mood improvement in sleep-deprived depressed patients.

The possible role of altered serotonin and calcium metabolism in production of the dysphoric changes observed must likewise be considered. The finding of markedly increased CSF 5-HIAA in three of four patients is consistent with earlier data from animals and human subjects. Recent evidence suggests that the increase in central serotonin turnover occurring with melatonin administration represents a compensatory response to a primary blockade of serotonin receptors by melatonin (9, 10, 55–57). Indeed, melatonin prevents release of growth hormone by serotonin (56, 57). The large increases in 5-HIAA in those patients who demonstrated the clearest worsening while receiving melatonin is consistent with studies showing that 5-HIAA in CSF decreases following various antidepressant treatments (58, 59).

Similarly, the elevation of CSF calcium associated with melatonin administration to the same three patients complements the finding that antidepressants may decrease CSF calcium (60). Several preliminary findings link the pineal to humoral calcium regulation: in rats, pinealectomy results in hyperplasia of the parafollicular (calcitonin-producing) cells of the thyroid (61) and hypofunction of the parathyroid (62), which can be restored to normal by administration of melatonin (63). In an attempt to synthesize these findings we would postulate that melatonin exerts a tonic inhibition of calcitonin release from the thyroid and other sites, possibly by blockade of serotonergic mechanisms involved in that release (64). It is also intriguing that in one patient restriction of dietary calcium, which may produce pineal atrophy (65), has been reported to lessen the duration and severity of acute episodes of periodic psychosis (66).

While this preliminary trial indicates that melatonin is ineffective as an antidepressant in this patient population and may even worsen mood in patients with moderate to severe depression, further exploration of the role of this neurohormone in affective and other psychoses appears to be indicated.

Thyrotropin-Releasing Hormone: Differential Antidepressant and Endocrinological Effects

BY FRANKLIN W. FURLONG, M.D., GREGORY M. BROWN, M.D., AND MADELEINE F. BEECHING, R.N.

In a double-blind study, three depressed subjects received thyrotropin-releasing hormone (TRH) on three successive days, and one subject similarly received placebo; all subjects were then given ECT. Two of the patients given TRH responded to ECT. One patient's reaction is of special significance because of her response to ECT, diminished thyroid-stimulating hormone response to TRH, increased growth hormone and prolactin response to stress, and antidepressant effect of TRH. These findings raise the possibility that previous conflicting reports about TRH's antidepressant effects stem from the combined study of endocrinologically distinct depressive subgroups and strongly suggest that there may be a specific subgroup that is responsive to TRH.

RECENTLY, THERE HAVE been conflicting reports that a hypothalamic substance, thyrotropin-releasing hormone (TRH), has an unusual antidepressant effect.

TRH is a tripeptide produced in the mammalian central nervous system. Prange and associates (1) and Kastin and associates (2) first studied the effects of TRH in severely depressed women with a diagnosis of manic-depressive disorder, depressed type, or involutional depression. In the double-blind crossover study of Prange and associates, each patient received a single dose of TRH or saline; this was followed 1 week later by a single dose of saline or TRH. In the double-blind crossover study by Kastin and associates, each patient received a daily intravenous injection for 6 consecutive days; for 3 successive days the patient received saline solution and for the next 3 days, TRH. These researchers agreed on the following findings:

1. TRH produced an antidepressant effect beginning 1 to 6 hours after infusion and lasting from several hours to 3 days.
2. Thyroid-stimulating hormone (TSH) (thyrotropin) response was, with one exception, markedly flat, although the patients were free of obvious endocrinological disorder.
3. Physical side effects were mild and consisted of variable flushing, nausea, and a sense of warmth; all of these side effects were often not present, and they could frequently be avoided by slow injection of TRH.

In these studies, unlike later ones, there were marked differences in response between patients receiving saline placebo and TRH. In the study by Prange and associates (1), saline was never superior to TRH, but TRH was superior to saline in 5 of 12 trials. In Kastin and associates' study (2), none of the patients improved during control testing but all patients receiving TRH improved, although 1 did not respond until the third infusion. Subsequently, in a study of normal women, Prange and associates (3, 4) confirmed that physical effects occurred within minutes while psychological effects were delayed; further, the intensity of the mental change was unrelated to the intensity of the side effects and negatively related to TSH response.

Following these studies, there were further positive results with TRH (5) but some conflicting negative findings as well. Ehrensing and associates (6) reported on 8 patients who had major depressions and who received either 1000 μg of TRH or saline for 3 days in a double-blind study. Only 1 patient improved substantially with TRH. Further single-blind administration of TRH for 7 days also failed to produce positive results in the sample. In spite of the lack of antidepressant effect, plasma TSH and prolactin responses to TRH were distinctly diminished in 3 of the most severely depressed patients. Similarly, Coppen and associates (7) showed essentially no antidepressant effect of TRH although again there was evidence that TSH response was impaired in some depressed patients. Other studies (8, 9) have also failed to show any statistical superiority of TRH to placebo in a variety of depressive disorders.

The purpose of the present study was two-fold. We wished to retest the earlier observations on the effects of a single TRH injection, repeated daily for 3 days, on the affective state of patients suffering from in-

At the time this work was done the authors were with Clarke Institute of Psychiatry, Toronto, Ont., Canada, where Dr. Furlong was Staff Psychiatrist, Dr. Brown is Head, Neuroendocrinology Research Section, and Ms. Beeching is Research Assistant. Dr. Furlong is now Coordinator of Research, Department of Psychiatry, Toronto Western Hospital, 399 Bathurst St., Toronto, Ont., Canada. Dr. Furlong is also Assistant Professor and Dr. Brown is Professor, Department of Psychiatry, University of Toronto.

This work was supported in part by a grant from Hoechst Pharmaceuticals, Montreal, Quebec, Canada, and by grant MT-4749 from the Medical Research Council of Canada. Dr. Brown received support as a Research Associate of the Ontario Mental Health Foundation.

TRH was supplied by Hoechst Pharmaceuticals. The authors wish to express their appreciation for the assistance provided by Ms. K. Bezchlibnyk, Pharmacist, Clarke Institute of Psychiatry.

volutional melancholia or endogenous depression (manic-depressive disorder, depressed type). In addition, we wished to study the association between clinical and hormonal response to TRH and affective changes during a subsequent course of ECT.

METHOD

Subjects

From the inpatient population of the Clarke Institute of Psychiatry, a university teaching hospital, we recruited all the patients who met the criteria for inclusion in the study and agreed to participate. They had all been diagnosed as suffering from either involutional melancholia or endogenous depression (manic-depressive disorder, depressed type) as judged by the treating psychiatrist and the research psychiatrist (F.W.F.) in charge of the project. The treating psychiatrist had made a previous independent clinical judgment that ECT was the treatment of choice for each patient's existing affective state. At the same time the treating psychiatrist believed that the delay in receiving ECT due to the TRH trial did not involve any significant hazard to the patient.

The subjects were physically normal. They showed no evidence of thyroid disease on the basis of physical examination, history, and laboratory tests (T_3 resin uptake and T_4). None of the subjects was an involuntary patient or was mentally subnormal. None showed any evidence of epilepsy, organic brain syndrome, or significant abnormalities based on laboratory tests and physical examination. The sample included only 1 woman who was of childbearing age; none of the female subjects was currently receiving hormonal medication. All of the subjects received a score of 20 or higher on the Hamilton Depression Rating Scale (10) at the time of the initial assessment and following a 3-day placebo washout period. After the nature of the study had been fully explained to them, all of the patients signed a statement of informed consent that had been approved by the university's committee on human experimentation.

Procedure

After a 3-day placebo washout period each patient was assigned to a group receiving TRH (N=3) or to a group that was to be treated identically except for receiving saline-placebo infusion instead of TRH (N=1). Assignment was done according to a matching procedure that was intended to achieve a rough balance for diagnosis, age, and sex if a larger number of subjects had been enrolled. The raters, nurses, and investigators did not know which patients had been assigned to each group; only the head pharmacist had this information. Placebo was the only medication given during the washout and infusion periods. During the period of ECT there were no restrictions on the use of medications. Prior to washout patient 1 received 30 mg of flurazepam at bedtime as needed, 5 mg of diazepam as needed, and 100 mg of amitriptyline once a day. Patients 3 and 4 received 30 mg of flurazepam at bedtime as needed, and patient 4 also received 5 mg of diazepam as needed and 200 mg of desipramine daily.

Each patient received an injection of placebo or 500 μg of TRH in saline solution, injected slowly over one minute; this procedure was repeated on 3 successive mornings. One or 2 days following the last injection the subjects were started on a course of ECT administered 3 times a week. The patients were supine during the first hour after the injection but were subsequently permitted to move about their rooms. A continuous intravenous drip was maintained for the first hour to permit painless removal of blood samples and was then discontinued.

The rater remained with the subjects for 6 hours following each of the 3 injections. The Hamilton depression scale was administered at the time the subjects were assessed for inclusion in the project and after washout, as well as just prior to injection and 4 hours after each injection. It was also administered on the morning following the last injection and on mornings following ECT sessions. The 10-cm scale, used essentially as described by Prange and associates (1), was completed immediately prior to infusion and hourly for 6 hours on each of the 3 injection days and subsequently whenever the Hamilton scale was administered. In this test a 10-cm line is drawn on a sheet of plain paper; one end (10 cm) is marked "As well as I could be" and the other end (1 cm), "As depressed as I could be." The patient marks where he stands at the moment of testing. The Zung Self-Rating Depression Scale (11) was administered at the same times. T_3 resin uptake and T_4 were repeated at the end of the injection period of 3 days, as were all of the standard laboratory measures. The patients' temperature, blood pressure, pulse, and respiration were recorded at the same intervals.

Plasma TSH, prolactin, and growth hormone (GH) were measured by double antibody radioimmunoassay using materials and directions supplied by the National Pituitary Agency, under a program supported by the National Institute of Arthritis, Metabolism, and Digestive Diseases. TSH, prolactin, and GH were measured 15 minutes before infusion, immediately before infusion, and at 15, 30, 45, and 60 minutes after infusion.

RESULTS

Table 1 summarizes the relationship between the patients' initial ratings and clinical and endocrinological responses to TRH and stress. The main interest lies in the relationship observed in 1 subject among marked subjective response to TRH, abnormal TSH response, marked GH and prolactin response to stress, and response to ECT.

Clinical Findings

Patient 1 was a 50-year-old woman with a diagnosis

TABLE 1
Relationship Between Initial Scale Ratings and Clinical and Endocrinological Responses to TRH and Stress

Item	Patient 1	2	3	4
Zung scale rating	60	40	34	28
Hamilton scale rating	43	22	35	46
Clinical response to TRH	Yes	—*	No	No
Clinical response to ECT	Yes	No	Yes	No
Mean maximum endocrinological response**				
TSH (μU/ml)	0.1	0.0	11.0	14.0
Prolactin (ng/ml)	82.0	4.7	78.0	17.0
GH (ng/ml)	22.0	0.0	3.0	0.1

*Patient received placebo rather than TRH.
**Mean of 3 responses. The criteria for response to TRH and stress was an increase of 5 μU/ml for TSH and 5 ng/ml for prolactin and GH.

of manic-depressive disorder, depressed type. The initial self-rating on the day of the first injection was 1 cm. She reported subjective improvement (rated at 5 cm) after the first injection; improvement reached a maximum at 1 hour and fluctuated thereafter. There was a similar response on the second day, with a peak of 6 cm at 4 hours. Infusion on the third day resulted in improvement from an initial score of 1 cm to a maximum of 7 cm at 4 hours. The Hamilton depression scale, administered at hours 0 to 4 on the days of the injections, recorded a corresponding rater-assessed improvement. During the course of ECT improvement was first noted after 2 sessions and maximum improvement after 3 sessions; the patient received a total of 8 sessions. All major symptoms of her depressive state remitted, and her Hamilton depression score dropped from 43 to a final score of 0. Scores on the Zung depression scale and the 10-cm scale were consistent.

Patient 2, a 50-year-old woman, had been diagnosed as suffering from involutional melancholia. She received placebo infusion. She noted a peculiar smell and taste during placebo infusion, which was probably suggested by the description of possible side effects in the consent form. She showed no beneficial response to the infusion and minimal response to the subsequent course of ECT. The significance of this subject for the study is the baselines she provided for establishing hormonal response.

Patient 3 was a 39-year-old woman suffering from manic-depressive disorder, depressed type, with a history of 2 previous depressive episodes responsive to ECT. She reported nausea 2 hours after the first injection. There was no evidence of any clinically consistent response to TRH injection. During the subsequent course of ECT she showed improvement after 4 sessions, with maximum improvement after 10 sessions. She received a total of 12 sessions.

Patient 4 was a 53-year-old man with a diagnosis of manic-depressive disorder, depressed type. He had had 3 previous admissions for depression, one of which had responded to a course of 9 ECT sessions. During the placebo washout period he complained of such side effects as dizziness, which he attributed to the placebo. There were no consistent changes in affect during TRH injection. The patient received a course of 8 ECT sessions with no clear-cut improvement, and ECT was discontinued.

Endocrinological Findings

In patient 2 (placebo) there were no alterations in TSH or GH (see table 1). Prolactin was elevated beginning 15 minutes after venipuncture on the first occasion just prior to injection of placebo.

Of the 3 subjects receiving TRH, patients 3 and 4 showed TSH elevation on each occasion, while patient 1 showed no TSH elevation. In patients 3 and 4 the TSH response diminished in magnitude on the second and third occasions, possibly because of feedback effects since it is known that increased blood thyroid hormone levels will decrease pituitary TSH response to TRH. These 2 patients also showed an elevation in prolactin. Of the 6 TRH injections that produced a TSH response, only 1 was accompanied by GH elevation. In the single subject (patient 1) who showed no TSH elevation in response to TRH, both GH and prolactin were elevated during each of the 3 sessions. GH and prolactin elevations paralleled one another on each occasion, and during 2 of the sessions the initial elevation preceded the injection of TRH. Patient 1 showed normal T_3 resin uptake and T_4 before and after the series of infusions and at the end of the course of ECT.

DISCUSSION

While previous studies have disagreed about the antidepressant effect of TRH injection, they have rather consistently reported an overall tendency toward flattened TSH response in some depressed patients. The relationship between abnormal TSH response and clinical response is neither consistent nor clear. This study also attempted to relate clinical and endocrinological responses to the effects of a subsequent course of ECT.

Kastin and associates (2) reported that TSH responses to TRH were markedly decreased in 4 of their 5 subjects and there was a marked overall clinical response to TRH. Prange and associates (1) reported that in 8 of 10 subjects TSH response was at the extreme lower limit of normal and in 2 patients it was lower. Coppen and associates (7) found no evidence for clinical action but reported that TSH response was impaired in some depressed subjects. There was a tendency for depressed female patients to demonstrate a reduced TSH response compared with control subjects. While those researchers reported no clinical response, the evidence for abnormal TSH response was

less striking than in the 2 earlier studies. Another study (6) found that TRH at doses of 1000 μg did not produce clinical benefit. Plasma TSH and prolactin responses to TRH were diminished in 3 depressed patients. The flattened TSH response to TRH seemed to correlate with severe endogenous and involutional depressions. The most severely depressed patients had a flattened TSH response. The only patient to show a significant clinical improvement while receiving TRH had a blunted TSH response. Ehrensing and associates (6) suggested that the prime value of TRH might be as a diagnostic tool in distinguishing among various subtypes of depression. In retrospect, it appears that the earlier studies that reported positive clinical effects tended to show more profound and pervasive abnormalities in TSH response.

We based the selection of our subjects on clinical diagnosis and an independent clinical decision to use ECT. The 3 patients given TRH fall into 2 distinct groups on the basis of both clinical and endocrinological responses. In patient 1 there was a clinical improvement, while in patients 3 and 4 there was none. It is known that both GH and prolactin levels rise in response to stressful stimuli (12, 13), while TSH and prolactin levels are elevated after TRH injection. Two studies of depressed subjects (5, 14) reported an elevation in GH levels after TRH injection. Despite these reports, we attribute the parallel rise of prolactin and GH in patient 1 to the stress of the procedure because the increase *preceded* the TRH injection on 2 of the 3 occasions. In subjects 3 and 4, TSH and prolactin responses after TRH injection paralleled one another and GH elevation was noted after only 1 of 6 injections, indicating that these prolactin responses were produced by TRH. In patient 1 marked GH and prolactin responses were noted with no response to TRH, while in patients 3 and 4 the reverse was true.

There was no overall evidence for a general antidepressant effect. In 1 patient, however, there was a clinical response that could have been a placebo effect. However, it may well be significant that this coexisted with several other features to which both patient and experimenters were blind, namely, no TSH response, marked GH and prolactin venipuncture responses (stress response), and subsequent marked and clear response to ECT after 2 sessions.

On the basis of this, it might be reasonable to hypothesize that TRH may be an effective treatment for a subgroup of depressed patients characterized by severity of illness, abnormal TSH response, accentuated GH and prolactin response to stress, and clinical response to ECT. The question also arises as to whether flattened TSH response to TRH could be characteristic of those depressions which respond well and quickly to ECT; such response is not a completely predictable clinical event. In general, blunted TSH response suggests an abnormality of the hypothalamic pituitary axis in some cases of depression.

Platelet Monoamine Oxidase Activity in Schizophrenia

BY HELEN L. WHITE, PH.D., MALCOLM N. MCLEOD, M.D.,
AND JONATHAN R.T. DAVIDSON, M.B., B.S., D.P.M.

The activity of platelet monoamine oxidase in 12 chronic schizophrenic patients was not significantly different from that in a matched group of normal individuals. The authors emphasize the importance of simultaneous processing of control and patient blood samples and the use of carefully controlled techniques, since relatively minor changes in procedure can markedly influence platelet yield and leucocyte contamination.

THE INITIAL REPORT that mean platelet monoamine oxidase (MAO) activity, assayed with ^{14}C-tryptamine as substrate, was lower in 33 chronic schizophrenic patients than in 22 normal control subjects has sparked considerable interest among clinical researchers and psychiatrists. However, efforts to confirm and further explore that finding have produced a confusing variety of data. Table 1 indicates that published mean values for both normal and schizophrenic individuals vary by a factor or more than 2 and that reported "normal" values have decreased over the years. Carpenter and associates (6) pointed out that platelet MAO was not significantly different from normal in 40 acute and 4 chronic schizophrenic patients, and Nies and associates (3) reported that MAO activity was not significantly lower than normal in chronic schizophrenics when benzylamine was used as the enzyme substrate, although they did see a difference when tryptamine was the substrate. Friedman and associates (4) observed no difference between platelet MAO values for normal and schizophrenic men; their mean value for schizophrenic women was lower than that for normal women, but the difference was not statistically significant. Zeller and associates (8), using tyramine as substrate, reported decreased platelet MAO in both male and female schizophrenics. Cookson and associates (9) reported that in one patient who exhibited a schizophreniform psychosis, platelet MAO activity, with tyramine as substrate, increased 39-fold during 2 weeks of successful therapy with haloperidol. However, they were unable to demonstrate similar changes in other schizophrenic patients. Shaskan and Becker (7) suggested that there may be a biphasic distribution of platelet MAO in both normal and schizophrenic subjects. A bimodal distribution among normal subjects was also observed by Nies and associates (10). In limited studies of autopsy tissue, Nies and associates (3) and Schwartz and associates (11) indicated that MAO is not lower than normal in brains of schizophrenic individuals.

Dr. White is Senior Research Pharmacologist, Wellcome Research Laboratories, 3030 Cornwallis Rd., Research Triangle Park, N.C. 27709. Dr. McLeod is Director, Eastern Unit, John Umstead Hospital, Butner, N.C., where Dr. Davidson is Staff Psychiatrist. Drs. McLeod and Davidson are also Clinical Assistant Professors, Department of Psychiatry, University of North Carolina, Chapel Hill, N.C.

METHOD

Because of the important implications for diagnosis and therapy, we attempted to confirm the observation of reduced platelet MAO activity in 12 chronic schizophrenic patients, diagnosed by the criteria of Feighner and associates (12), compared with 12 normal individuals (hospital personnel). Mean ages were 39.8 and 37.3 years for the normal and schizophrenic groups, respectively, with 6 men and 6 women in each group. Table 2 presents relevant clinical information on the patients. All showed disrupted interpersonal relationships. None of them was married at the time of admission; 9 of the 12 had never been married. All had extensive hospitalization, with duration of the illness ranging from 4 to 34 years. All were on medication. Although Feighner's criteria were used, these cases also manifested Schneider's first-rank symptoms, such as primary delusions and passivity phenomena. In most cases their employment record was unsatisfactory or nonexistent.

After informed consent had been obtained, blood samples (10 ml) were drawn into plastic syringes that contained 0.2 ml of 10% EDTA at pH 7.4. Control and patient samples were obtained in the hospital at the same time and were kept at ambient temperature for no longer than 2 hours before separation and washing of platelets at 8–10° C by the procedure of Robinson and associates (13). All of the patients were receiving major tranquilizers, but these drugs have been found not to influence MAO values (1). However, since chlorpromazine has been found to weakly inhibit the oxidation of phenethylamine by rabbit brain MAO (14), the influence of that drug is still in doubt. Platelet suspensions were frozen at −20° C immediately after preparation. MAO was assayed with ^{14}C-tryptamine (10^{-4} M, 8.3 mCi/mmol) as substrate in the procedure of Wurt-

man and Axelrod (15). All samples were assayed in duplicate. Blank assays for each platelet preparation were performed with a concentration of 2 mM pargyline to block MAO activity. Counts per minute obtained in assays of platelet MAO were corrected by subtracting these blank values.

RESULTS

We found no significant difference in mean platelet MAO activity between chronic schizophrenic and normal individuals. This was the case whether results were expressed as counts per minute of ^{14}C-product, as nanomoles per hour per milligram of protein, or as nanomoles per hour based on milliliters of original whole blood. We preferred the last measurement because of possible variations in leucocyte contamination of platelet extracts and because plasma platelet concentration (i.e., amount of platelet protein) may easily vary by a factor of 2, so that enzyme activities based on milligrams of platelet protein may not accurately reflect the concentration of MAO in an individual's blood. Mean values for platelet MAO (±SE)

were 0.078±0.019 and 0.083±0.027 nmol/hour per ml of whole blood equivalent for normals and schizophrenics, respectively. Since the yield of washed platelets (about 0.5 mg of platelet protein from 10 ml of blood) was probably much less than 100%, these values would not represent the true amine-metabolizing capability of human blood. Mean values based on platelet protein were 2.0±0.8 and 1.8±0.3 nmol/hour per mg for normals and schizophrenics, respectively.

DISCUSSION

During the course of this study it became obvious that experimental values for platelet MAO varied markedly with different methods of extract preparation. With minor changes in procedure, the same sample of blood may produce a platelet extract with a protein concentration that could vary up to a factor of 10, depending on the extent of leucocyte contamination. Most workers express platelet MAO based on milligrams of protein. This may explain the large discrepancies seen in table 1, especially since blood samples were sometimes processed at different locations for the same study. When a different centrifugation procedure (in which the washing of platelets was eliminated) was used, experimental MAO activities, expressed as nanomoles per hour per milliliter of whole blood, were up to two times higher because the yield of platelets was higher. However, when expressed as nanomoles per hour per milligram of protein, the MAO values were 5 times lower because protein concentration in the extracts was greater. This emphasizes the importance of simultaneous processing of control and patient blood samples and the necessity for critical attention to experimental conditions in studies of this nature.

CONCLUSIONS

Although a depressed MAO activity in some schizophrenic patients may be consistent with a possible overactivity of dopaminergic pathways (16) and is very likely influenced by genetic factors (2, 10), the suggestion that an assay of platelet MAO might be used as a laboratory indicator of vulnerability to schizophrenia (2) does not appear justified.

BRIEF COMMUNICATIONS

Treatment of Requests for Sex-Change Surgery with Psychotherapy

BY MARTHA KIRKPATRICK, M.D., AND CLAUDE T.H. FRIEDMANN, M.D.

The authors describe two patients whose requests for sex-change surgery represented crises in sexual identity and anxiety-masking symptoms. Brief psychotherapy enabled these patients to relinquish their belief in a surgical "cure." In evaluating such requests, the psychiatrist should consider the patient's total personality rather than focusing on the genuineness of the perceived gender disorder. Whatever the final decision, the opportunity for continued psychotherapy should be provided.

THERE HAS been keen interest in the problem and treatment of transsexualism since the Christine Jorgensen case in 1953, and sex-reassignment surgery has become an exciting area of surgical innovation. Harry Benjamin's book *The Transsexual Phenomenon* (1) emphasized the improvement in social comfort, self-esteem, and the capacity to relate that many male transsexuals experienced after such surgery. He recommended that selection for surgery be determined by the personal history, the capacity to adapt to a female life-style (usually demonstrated by reaction to hormone therapy, electrolysis, and a one- or two-year trial of living and working as a woman), and psychiatric evaluation. Centers such as those at the University of California, Los Angeles, Johns Hopkins University, and Stanford University were established to provide services to transsexuals, and psychiatrists who had rarely been consulted by patients with such problems had the opportunity to learn about this phenomenon.

Dr. Kirkpatrick is Associate Clinical Professor, Department of Psychiatry, University of California, Los Angeles, where Dr. Friedmann was a second-year resident at the time this work was done. Dr. Friedmann is now Adjunct Assistant Professor, Department of Psychiatry, University of California, Los Angeles, and Chief, Adult Psychiatry Outpatient Department, Harbor General Hospital, Torrance, Calif. Address reprint requests to Dr. Kirkpatrick at 988 Bluegrass Lane, Los Angeles, Calif. 90049.

Although surgical treatment for transsexuals was originally greeted with skepticism, Newman and Stoller (2) note that "the pendulum may have swung too far in the other direction." Stoller (3) also pointed out that "The most troubling aspect [of surgical treatment] is that the easier it is to have such procedures done, the more patients request them." Moreover, Baker and Green (4) and Newman and Stoller (2) have cautioned that a wide variety of patients who present as transsexuals may not actually have a deep gender disorder. Benjamin (5) stressed the potential for iatrogenic influence on such requests.

Newman (6) and others have pointed out that there are no reports of clearly defined cases of transsexualism that have been successfully treated by psychotherapy. Although therapy was reported as "helpful" in one case (7), there seems to be general agreement that the true transsexual is rarely available to psychotherapeutic intervention (4, 6). We are concerned that these statements may discourage the practitioner from approaching the initial interview with such patients in a way that could lead to recommending or continuing psychotherapy. The dramatic nature of the request can also divert the physician from his/her usual interest in the whole personality. This is a disservice to the patient. Many patients who request sex-change surgery, such as the two we will describe below, are not true transsexuals and can benefit from conscientious psychotherapy.

CASE REPORTS

Case 1. An 18-year-old woman wrote for an appointment to discuss the possibility of sex reassignment surgery. Her letter stated,

> I have felt like a male all my life. And all my life I have dreamed that I could be changed completely into a male. Up until about six months ago I had no idea that such a change was possible. I guess I don't have to tell you, when

I found out it was possible, it made my whole world a lot clearer, and something to look forward to for the life time of future happiness, to be able to stop pretending I'm something I'm not.

She came to the interview in cowboy attire, short hair, and no makeup. She was tall, gangly, and flat chested. She had always been a tomboy and had friends of both sexes, but her sexual relationships were confined to women (her first sexual experience was with a girlfriend at age 4). She never allowed a female sexual partner to enter her vaginally. She believed she had a fluid emission like an ejaculation at climax, and thought she might have a penis inside her body. Her menstrual periods were always accompanied by severe pain. During her early life, her family had been involved with a fundamentalist religion. She believed God would condemn homosexual relationships and thought that the surgical change would make her sexual life less sinful.

The patient soberly accepted the information that she was mistaken in her belief that a penile prosthesis could be satisfactorily constructed from skin. She elected to continue psychotherapy consultation once a week. Despite a 2½-hour drive to the therapist's office, the patient came to her appointments regularly for 1½ years. The subject of surgical treatment did not come up after the first two visits; her major concern was a homosexual relationship that was on the verge of dissolution. The request for surgery was an attempt to allay this loss and the depression it evoked. The relationship did end, and she weathered the loss and gained self-esteem as a result of her ability to do so.

Her therapy centered around the feelings of disappointment and rage she experienced when she discovered at the age of 4 that her father, whom she idolized, favored her older brother.

In the last 6 months of therapy, an interest in sociology led the patient to enter junior college, where she did creditable work. Her homosexual relationships continued but were less intense, and she was better able to tolerate separation and loss. When last heard from, she had completed her course and was applying for a job in a social work agency as a female.

Case 2. A 19-year-old Catholic male presented himself for psychiatric evaluation, stating that he had always felt like a woman and had wanted a sex change since he was 16. He denied any acute precipitating factors for the request. He had, however, entered a university 2 months earlier. The patient came to the initial interview in women's jeans and a blouse, but he wore no makeup and his gestures were masculine by contemporary standards. He spoke softly and seductively.

He had started cross-dressing before he was 5 years old with the help of his three sisters. He always dressed as a woman on Halloween. He began wearing women's pants and shirts in public at age 16, but he wore dresses, slips, and skirts only to costume parties or in private. His cross-dressing had initially been sexually exciting, but this had not been the case during the past 5 years.

He had dated several girls since the eighth grade and reported oral sexual contact with some of them, but he had never had an erection with a woman. All of his masturbatory fantasies and orgastic experiences were about or with men. He tended to play a female role for physically strong homosexual men; he saw them as "straight" men who looked upon him as a woman. It is important to note that the patient considered his penis a source of pleasure and wanted to be sure that a vagina would suit him. He therefore thought it was a good idea to spend a few months discussing the pros and cons of surgery with a psychiatrist before making an irreversible decision.

The patient participated in individual psychoanalytically oriented outpatient therapy twice a week for 15 weeks. The therapist made no value judgments about the patient's sexual preference and steered the therapy away from the sexual issue per se, inviting the patient to be introspective and to discuss other issues more fully. After several superficial attempts, the patient explored his relationships with his parents, sisters, and friends. He spoke of his femininity as a way to avoid competition with his father and other aggressive men and to rebel against their expectations. He considered men to be physical and women emotional. He saw sexual intercourse as exploitation of men by women and vice versa. He began to consider himself exceedingly superficial and incapable of any deep relationships. In the therapeutic relationship, he was passive and "effeminate" when angry. The patient also dealt with problems of identity, life goals, college and jobs in therapy.

Approximately 10 weeks after therapy began, the patient started to dress in masculine attire and appeared more assertive in his feelings and ideas. By the 13th week, he declared himself a "man"; he decided he was a homosexual and wanted to keep his penis. He did not want to explore his feelings further at this point and terminated treatment 2 weeks later.

DISCUSSION

The male patient we described could have met the diagnostic criteria for transsexualism had he stated that he got no sexual pleasure from his penis or from earlier cross-dressing. Thus, if the patient had been more well-read or known some true transsexuals, his history might have been totally convincing. As Benjamin (5) rightly states, "Many patients know too well what their story has to be in order to get [surgery]." Furthermore, had the therapist been satisfied with a "diagnostic consultation," he might have rejected the request for surgery, but overtly or covertly given clues that would have enabled the patient to present a better story the next time. Even Christine Jorgensen was not sure of her identity until she read a number of medical journals (8). As Benjamin (5) noted, one should be extremely cautious when making a decision about any patient whose true gender identity is in doubt, and a request for sex reassignment should never be rejected outright without offering medical or psychiatric treatment (5).

The first patient might have been harder to diagnose, because the criteria for transsexualism in women are not established. There are some who doubt the existence of female transsexualism as an entity (9); however, this young woman presented a story similar to those of men who are considered transsexual and of women who would be so diagnosed by those who believe there are female transsexuals. Irreparable harm could have been done if either patient had had surgery. Bieber (10) presented a case report of a man who did not fit the currently accepted diagnostic criteria for transsexualism but was given surgery. Two years later

he committed suicide. Benjamin (5) emphasized that there is also a risk of suicide in patients who consider surgery their only answer but do not meet diagnostic criteria and are rejected without being offered alternative treatment. The therapist who is in doubt must remember that time is on his side. A true transsexual will last a year's test living as a member of the opposite sex, but an individual with a shallower cross-sexual identification will not (2).

Stoller (3) has written eloquently about the psychodynamics of true transsexuals. Less has been written on the dynamics of the transsexual symptom. Newman and Stoller (2) reported on four patients who presented as transsexuals: two were fetishistic cross-dressers, one was psychotic, and one was homosexual. The homosexual was in a crisis over the loss of a lover, and one of the fetishists had been left by his wife. In the other two cases, the crisis was not clearly defined. Dellaert and Kunke (11) described the case of a man who had a transsexual crisis upon entering the army. Both of our patients were probably in crisis, one over entering college and the other over the loss of a homosexual partner.

One of us (M.K.) was consulted recently by a 56-year-old man who has been married for 25 years with no history suggestive of gender disorder or variant object choice, sexual role, or social role. For the past 18 months he had had an increasing desire to have "a smooth pubis like a woman's." This desire followed a series of severe personal losses, including loss of his job, which resulted in his wife supporting him. His wife had lost sexual interest in him at a time when she was intensely preoccupied with their son, who had experienced a psychotic break.

We feel very strongly that in the three individuals we have described, the transsexual ideation is a defense against anxiety, not a core gender identity disturbance.

The first two patients had conflict about their homosexual orientation that was exacerbated by new stresses in their lives. The surgical solution was sought to minimize this conflict rather than to treat a gender disorder. While neither of our patients elected to pursue any in-depth investigation of their homosexual feelings, psychotherapy helped them with their crises. We believe that they will seek therapy in future times of anxiety rather than demanding a surgical cure.

We believe it is important to distinguish between the transsexual syndrome for which sex-reassignment surgery may be the only useful therapy and the transsexual symptom that can benefit from psychotherapy. Quick external cures have always been preferred to the slow, uncertain internal growth of psychotherapy. In our experience, the symptom is usually associated with an attempt to avoid the pain of a loss that is experienced as gender-related. A change to the idealized or invulnerable opposite sex is seen as a protection from loss. The therapist can identify the loss and support the patient in facing it.

Many workers (2, 5, 10) have emphasized that the nature of the transsexual request must be evaluated carefully before surgery is recommended. We want to emphasize two additional points. First, dealing with the transsexual request by pursuing questions about sexual and gender identity may convince the patient that the psychiatric consultation is a trial in which surgery must be won. The patient is thus denied an opportunity to develop an introspective attitude toward the consultation. In taking this approach, we may be inadvertently teaching the patient how to present himself or herself as a transsexual and to ignore the rest of his/her personality, denying problems that do not have a surgical solution. Second, the transsexual request should be evaluated not only in terms of the genuineness of the gender disorder but also as a cry for help. It may be the patient's way of manifesting a need for crisis consultation. The clinician can help the patient to identify the crisis and make use of psychotherapy in dealing with it.

The transsexual request is a request for treatment, and psychotherapy should be recommended for the overt or covert anxiety. If the decision has been reached to try a year living and working as the opposite sex preparatory to surgery, psychotherapy during the waiting period is valuable and should be offered.

Peer Counseling in a General Hospital

BY FREDERICK G. GUGGENHEIM, M.D., AND SUZANNE O'HARA, R.N., M.S.

Self-help groups can aid an individual in coping with and adapting to catastrophic illness. The authors describe a therapeutic technique in which a member of a medical team serves as a catalyst in introducing a "veteran" patient to a newly disabled patient with the same disease or problem so that they can share feelings, experiences, and strategies. Two cases are presented in which patients who were severely depressed benefited from peer counseling. Short-term or "one-shot" encounters can be a valuable way to help some disabled patients deal with the anxiety and helplessness they feel in the acute states of serious disease or injury.

PEER HELP, organized outside the traditional health care framework, has been an important therapeutic modality for several decades (1). Prominent self-help groups include Alcoholics Anonymous (2), Recovery Incorporated (for patients with mental illness) (3), TOPS (for patients with obesity) (4, 5), Ostamates (for patients with colostomies) (6), and Widow-to-Widow (7).

In most general hospitals, patients often help each other on an informal basis—only rarely is such interaction arranged by the hospital care-taking teams. The following cases represent instances in which significant support was given in a planned therapeutic approach that brought together two patients with similar illnesses, one who had recovered from its major effects and the other who was in the initial stages of the illness.

CASE REPORTS

Case 1. Ms. A, a 53-year-old housewife and mother of four, was hit by a truck while touring with her family in a foreign country. She immediately sustained a traumatic above-knee amputation of her left leg and severe crush injury to her right leg. One week later, she was flown to Massachusetts General Hospital for treatment of gangrene that was developing in her right leg. Before the accident, Ms. A was a healthy, outgoing, independent, open person, involved in her community and devoted to her husband and children.

On admission to Massachusetts General, she appeared mildly depressed as she focused on details of her accident. She became seriously depressed over the next two months as multiple medical complications made it increasingly evident that she would lose her remaining leg. Despite active staff support and family encouragement, she became deeply enmeshed in self-pity and bitterness. She experienced sleeplessness, decreased appetite, and apathy. Administration of 150 mg/day of amitriptyline for the next 4 weeks did not produce an appreciable improvement; in fact, her depression increased. The psychiatric nurse clinician suggested peer counseling. Ms. A's physicians were reluctant initially, but the patient's progressive depression, without any other means of effective treatment, prompted them to allow a therapeutic trial.

On another unit there was a 36-year-old married accountant, Mr. B, who had sustained bilateral above-knee amputations 20 years earlier. He used his leg prostheses until an intercurrent illness forced him to use his wheelchair again. After learning from the psychiatric nurse clinician about Ms. A's predicament and needs, Mr. B agreed enthusiastically to the encounter. Ms. A agreed to the meeting.

The psychiatric nurse clinician introduced Ms. A to Mr. B and his wife. All four participants were tense as Ms. A opened the session by asking, "How do you manage to live in a wheelchair?" Mr. B responded by talking about the difficulty of his initial adjustments. He said that he had resented his condition until he began to think, "I'm better off like this than dead. It's all I have. I had better adjust if I want to live normally." He began to boost his own morale and acknowledge the help he received from his family, who were able to treat him as an individual and not a "china doll." Mr. B shared his feelings about encountering embarrassing situations and demonstrated his mobility in and out of the wheelchair.

Both patients related details of their accidents and phases of their adjustment, and genuine closeness evolved through humor and serious talk. The psychiatric nurse clinician helped set the tone of the session and bridged communication gaps. She asked questions when the patient seemed hesitant to discuss certain issues that were important to her, e.g., how to minimize the financial drain and how to diminish social embarrassment.

In concluding the interview, Mr. B addressed Ms. A's discouragement by saying, "You're only as limited as you limit yourself. Naturally, I'd much rather have my own legs than be in a wheelchair but then again I'd rather be rich than poor." Ms. A said she would have to "learn to be an invalid in a wheelchair," and Mr. B quickly replied, "I'm not an invalid! I consider myself handicapped, living a normal life." Later they parted with a feeling of warmth that accompanies a shared, moving experience. Mr. B subsequently said he was grateful to have had this opportunity; he realized how much he had helped Ms. A. On follow-up Ms. A said, "I felt that it was extremely worthwhile to watch him and his wife's acceptance of him and to see him as a well-adjusted person even though he has no legs. I was amazed and would not

Dr. Guggenheim is Director, Private Psychiatric Consultation Service, Massachusetts General Hospital, Box 70, Boston, Mass. 02114, where Ms. O'Hara is a Psychiatric Nurse Clinician. Dr. Guggenheim is also Assistant Professor of Psychiatry, Harvard Medical School.

have believed it if you had just told me. But I believe it because I saw him." During her lengthy rehabilitation, she often reflected on Mr. B's successful adaptation and said it increased her motivation to persevere.

Case 2. Mr. C, a hypochondriacal 56-year-old factory worker and physical fitness enthusiast, was hospitalized for infectious polyneuritis. His Guillain-Barré syndrome produced almost total paralysis, and he required assisted respiration for the first two weeks. Concomitantly, his depression increased from mild to severe. He wished for death as a way out of his predicament, but he was fearful of it. He asked repeatedly to be disconnected from the mechanical apparatus so he could die peacefully. As he began to recover, the staff was disconcerted to find that their encouraging comments about his potential for full recovery were greeted with mounting suspicion. He refused to be weaned from the respirator; he would not try to cough or cooperate in other aspects of his pulmonary care. He was convinced that he had a terminal illness because his brother had died recently with paralysis from metastases to the spinal cord.

Because of his rapidly mounting depression and unresponsiveness to staff interaction and psychoactive medication, the team thought that Mr. C might benefit from talking with someone else who had recovered recently from the same disease. The house officers were pessimistic about the usefulness of this procedure because of the depth of Mr. C's depression, but they agreed to have the psychiatric nurse clinician introduce him to a former Guillain-Barré patient. Mr. D, a 36-year-old married tradesman and jogger who had recovered fully from the disease, agreed to talk with the patient. Mr. C thought that such an encounter would be useless, but he did not protest. His wife was eager for the meeting.

The psychiatric nurse clinician summarized Mr. C's principal concerns and background for Mr. D and gave him an informal agenda. In the meeting she acted to facilitate communication, steering Mr. D's conversation away from herself and toward Mr. C, who was able to talk in limited amounts. Mr. D was the most active participant. He reflected on the unbearable length of time it had taken him to communicate, the impatience he and his family had felt as a result of the slowness of his recovery, the loneliness of being unable to express feelings or ideas, and the frequent frustrations and irritability. Mr. D pointed out how staff and family had helped him and mentioned how burdensome it was to realize that rehabilitation is really up to oneself.

Mr. C's immediate crisis was communication, and Mr. D discussed some of the techniques he had used to inform staff of his needs. He had learned to pantomime messages and feelings and to use cards when he could not talk or write. He also told Mr. C that there was no permanent damage from the disease and mentioned his increasing appreciation of life in the postrecovery phase, with the experience of real independence. The former patient told Mr. C that the illness had brought him closer to some friends he had not seen in years and had facilitated a new openness in family relationships. Mr. C and his wife asked questions about personal reactions to various events in the recovery phase, about posthospital financial difficulties that needed to be arranged, and about returning to the job.

At the end of the meeting, Mr. D gave the patient his telephone number and shook his hand. A warm feeling was generated by their sharing of important fears and desires.

There was a drastic change in Mr. C's attitudes and behavior within several hours after the encounter. He became more cooperative with staff during the painful respiratory therapy treatments and his pulmonary function studies showed dramatic improvement. He began to accept more responsibility for his role in his recovery. His depression lessened, although he still had brief episodes of despondency. After 5 months of hospitalization, Mr. C was discharged. He spontaneously emphasized the importance of peer counseling as a primary aid to recovery and offered to act as a "recovered" patient should the need arise. Mr. D was very pleased to have served as a resource person, and the two men have continued their relationship since Mr. C's discharge.

DISCUSSION

The prospects of a disabling or disfiguring illness can fill a patient with dread and despair. We have observed that two particularly troublesome issues for many severely ill patients are fear of the unknown and the absence of any meaningful model for successful adaptation. The timely introduction of a patient who has traveled the rigorous, frightening pathways of disease may do much to facilitate coping, as the two case reports have illustrated.

At this point, several caveats should be mentioned. For a meaningful interaction between a newly disabled patient and a successfully coping "veteran," the staff must consider certain conditions.

1. *Agreement.* The patient must agree, even if half-heartedly, to see someone with his disease.

2. *Timing.* The patient must have moved beyond shock and denial. If he has entered into a state of marked perturbation or repudiation of help, his ability and desire to attend and absorb may be diminished.

3. *The "veteran."* The former patient has to be enthusiastic, articulate, and believable. Similarities in cultural, economic, and educational background as well as age and sex are helpful, although apparently not vital.

Previous clinical experience has indicated that patients whose personalities are dominated by passivity, stoicism, and lack of imagination (8) or who have premorbid extremes of schizoid, paranoid, unstable, or inadequate traits (9) are not good candidates for rehabilitation. The question of whether peer counseling can be effective among such subjects needs further investigation and is beyond the scope of these pilot observations.

The therapeutic task of the newly disabled individual is to contend with and develop some sense of mastery of his disability. Encountering a patient who has coped successfully can help the recently disabled patient to perceive himself as handicapped rather than as an invalid. Peer counseling, in certain instances, has the capacity to cut through overwhelming anxiety and move a patient from hopelessness to motivation and to shift his/her perspective from one of self-pity to self-improvement. As is the case with self-help groups, the emphasis is not on deep psychotherapy, but on faith, will-power, self-control, and day-to-day victories (3).

Traditionally, medical personnel try to reassure the

newly disabled, but their comments are often dismissed as irrelevant. Moreover, staff encouragement of the disabled person to "accept" his illness often falls short of the mark, as is shown in the following statement by a recently blinded woman (10).

> I do not believe that an individual ever accepts blindness. Acceptance implies compliance and approval. However, adaptation to blindness is ongoing because the individual will continually meet unfamiliar situations. . . .
>
> I prefer the concept of "identity integration" to that of acceptance. I describe identity integration as a state of self-actualization in which the individual has learned to live with his disability, to acknowledge his limitations, to involve himself in a world outside of himself, and to return to the fulfillment of life goals. An individual who has achieved identity integration does not deny his feelings and expresses such feelings in constructive ways. Individuals who are self-actualizing, flexible, and spontaneous continue to grow. . . .

CONCLUSIONS

Questions and fears confront the recently disabled person as he faces uncharted pathways. Seemingly mundane but significant concerns can be responded to by the successful "veteran," who serves as a credible role model in the task of adjusting to a new identity.

Although variations of formal psychotherapy do have a place in the management of selected patients on medical-surgical wards (11–15), many times it is best to use a friendly, familiar, here-and-now approach, dealing with reality issues and their interpretation. This paper describes peer counseling as an important technique that, in addition to traditional psychotherapy, hypnosis, drug therapy, and milieu management, can be used in an acute general hospital when staff motivation makes little impact on the patient. It can also be an adjunct to a successful rehabilitation effort.

The Psychiatric Resident as an Ex-Officio Community Board Member

BY ALLAN BEIGEL, M.D., ROBERT BEVAN, M.D., JOHN LAWALL, M.D., JANET ORTTUNG, M.D., AND DENNIS WESTIN, M.D.

The authors describe a program in which third-year psychiatric residents participate as ex-officio members on the boards of community service agencies. Experience as board members gives residents a broad understanding of issues related to the delivery of community mental helth services and encourages them to continue community involvment after their training is completed.

DURING THE PAST 12 years, training in community psychiatry has emerged as an integral part of all psychiatric residencies. Taking a cue from some of the post-residency programs that began to develop in the early 1960s, training directors have begun to devise mechanisms for exposing a psychiatric resident to the community through direct clinical involvement, most commonly in community mental health centers. In an excellent review article, Pattison (1) outlined the following critical issues: 1) training for practice, 2) integration of training, 3) prerequisite clinical skills, 4) timing of training, 5) types of training experiences, 6) supervision of training, 7) training models, 8) training content, and 9) collaborative training.

At the University of Arizona College of Medicine, involvement of the psychiatric resident in a community mental health center is a part of the second-year clinical experience. Residents are also encouraged during the third-year program, which is largely elective, to involve themselves under supervision in other community settings such as the schools, the courts, the department of welfare, and the department of probation. With this exposure, it is our belief that a resident can later move into the community and begin functioning as a community psychiatrist, if that is his or her choice.

It should be recognized, however, that most residents who are exposed to a community psychiatry experience during training will not choose the primary professional role of a "community psychiatrist." Rather, they will move into one of the other common bases for psychiatric practice such as private practice or hospital-based practice.

Consequently, we became concerned about how a residency training program might prepare those who do not choose community psychiatry for greater community involvement, regardless of their primary mode of practice. We believe that the involvement of only community psychiatrists in the community is not sufficient if psychiatry as a profession is to play a role in the determination of community objectives, goals, and directions in regard to psychiatric and mental health services. Rather, all practicing psychiatrists should be interested, willing, and able to involve themselves in community affairs.

With a view toward achieving this goal, a seminar was developed in the third-year residency program that was designed not only to acquaint psychiatric residents with academic and clinical issues regarding the delivery of community mental health services but also to provide them with an experience as a professional member of the community. It was hoped that the residents would thus gain a greater appreciation of the complex social and political processes involved in the delivery of mental health services and would participate in these processes as informed and interested citizens after completion of training.

THE RESIDENT AS A COMMUNITY BOARD MEMBER

Each resident is asked at the end of the second year to select one agency where he or she will serve as an "ex-officio board member" during the third year of residency. The list of available agencies is drawn from all human service agencies in the community except those in which the resident is currently serving in a clinical capacity and those operated by government agencies. However, residents may select an agency in which they have worked in the past. The resident who does this has a unique opportunity to view mental health service delivery from a dual perspective.

The following agencies in the community have been

Dr. Beigel is Associate Professor, Dept. of Psychiatry, University of Arizona College of Medicine, Tucson, Ariz.; Dr. Bevan is Staff Psychiatrist, U.S. Army Medical Center, Fort Gordon, Ga.; Dr. LaWall is Medical Director, Tucson South Behavioral Health Services, Tucson, Ariz.; Dr. Orttung is in private practice and is Staff Psychiatrist, Tuscon Child Guidance Clinic; Dr. Westin is in private practice and is Staff Psychiatrist, Palo Verde Hospital, Tucson, Ariz. used: 1) a family service agency, 2) a community mental health center, 3) a children's residential and day treatment program, 4) a drug-abuse umbrella agency, and 5) the community services division of the local United Way organization. All are voluntary nonprofit agencies with policy making boards.

Each agency offers the resident a unique experience as an ex-officio board member. The family service agency provides better understanding of the relationship between medically oriented community mental health services, often found in community mental health centers, and nonmedically oriented family services. By comparing these two settings, the ex-officio board member can see the problems associated with integrating different organizational and service models into an effective system. Furthermore, he or she has the opportunity to assess the conflicts that often exist between different professional groups involved in service delivery.

The resident who chooses a community mental health center has an opportunity to participate in discussion about the critical financial problems that are affecting the delivery of services. Involvement in these processes provides a better understanding of how services are influenced by local, state, and federal bureaucracies, with their rules and regulations. Personnel management problems, particularly from the organization director's point of view, are also frequently encountered.

The resident who participates as an ex-officio board member in a children's residential treatment program can assess some of the special difficulties of providing adequate services to a specific target population. Exposure to these problems provides a better understanding of the continuing frustrations that accrue to those residents who attempt to maintain an important, but often underemphasized, service. In an independent children's program, the resident can also observe why quality programs for this age group tend to be so expensive and how service demands must be balanced against priority setting and accountability requirements.

The resident who selects the drug-abuse umbrella agency can explore a wide variety of issues related to the integration of mental health and substance abuse services. This experience allows the resident to come in contact with some of the negative community attitudes toward substance abusers and the pressures these create on board members of drug abuse programs.

Finally, the resident who participates in the United Way process is exposed to a broader perspective regarding the relationship between mental health services and the entire range of health and human services that a United Way umbrella encompasses. The resident and his fellow board members focus on planning issues and what must be done to integrate human services more effectively. This experience may also reveal that mental health services, as important as psychiatrists think they are, may be designated by the community as having a relatively low priority in comparison with other human services.

DISCUSSION

The response of residents who have participated in this experience has been gratifying. Several have shared the information that prior to the program they had little idea of what boards accomplished and only the vaguest suspicion of their range of activities. Others had preconceived notions that those who chose to become involved in boards were prominent people within the community who acted simply as prestigious figureheads. All found, however, that boards, which were most often a combination of professionals and nonprofessionals, were asked to deal with extremely important issues that greatly affect mental health services.

The psychiatric residents also found that they had to redefine their role to adjust to their new status. Previously, while working as clinicians in community mental health settings, their professional role had conferred special status. In a board setting, with many nonprofessionals involved, they found their position less certain and their expertise limited in regard to many of the administrative issues raised. They had to develop constraints on their participation, speaking out only on those issues about which they had expertise, remaining silent in other areas, or shedding their professional garb when they wished to discuss subjects about which they did not have expertise. Those who chose the latter course often had to spend extra time learning the complexities of the agency as well as basic management concepts so that they could communicate with other board members in their "language."

Residents who participated in this experience also came away with a greater respect for the dedication of those people in the community who involve themselves in board operations and a better understanding of what makes a board member effective (2). The potential for a resident's continuing involvement with the community, regardless of the area of practice chosen after training, has been increased. (One resident has already been elected a voting member of his board after the completion of training.)

Although some residents found participation in an ex-officio status frustrating because they had no formal vote, this barrier might prove useful since it may provide the resident with the necessary impetus to obtain voting status through continuing participation after the training experience. This early exposure may also help to counter the tendency of psychiatrists to isolate themselves in their professional practice or to claim that they are "too busy" to participate in community affairs.

Residents also found that didactic material in seminars on administrative and community psychiatry was more relevant as a result of their experiences as ex-officio board members. Discussions regarding the selec-

tion of board members, the relationship between board members and staff (3), the different functions and structures that boards assume, and the relationship between board processes and community social structure were placed in a more meaningful frame of reference as a result of the residents' participation on the boards selected. Furthermore, from the board level the residents were able to gain a better perspective of how mental health services are viewed by the community and how their effectiveness is determined by their relevance to community priorities and attitudes (4).

The Use of Two-Way TV in Bringing Mental Health Services to the Inner City

BY NORMAN STRAKER, M.D., PATRICIA MOSTYN, M.A., R.N., AND CARTER MARSHALL, M.D.

The authors describe a cable TV link between a medical school and a child health station in East Harlem. Nurse associates and community health workers trained through television conferences with a child psychiatrist have the primary responsibility for patient care at the clinic. Patients and their mothers are evaluated by the child psychiatrist in TV consultations at which nurse associates, health workers, medical students, and child psychiatric fellows are present. Patients and mothers respond positively to the system, and a high percentage of the psychiatrist's treatment recommendations are accepted. The authors suggest that such TV links can increase mental health services to underserved inner-city children.

The authors are with the Mount Sinai School of Medicine, New York, N.Y., where Dr. Straker is Assistant Clinical Professor, Dept. of Psychiatry, Ms. Mostyn is Psychiatric Nurse, and Dr. Marshall is Associate Professor, Department of Community Medicine. Address reprint requests to Dr. Straker at 9 East 96th St., Suite 6C, New York, N.Y. 10029.

This study was supported by a grant from the Grant Foundation. The authors wish to thank Nicholas Cunningham, M.D., and Kim Thomsted, R.N., Codirectors of the Wagner Child Health Station, and Ed Wallerstein, Coordinator, Department of Communications, Mount Sinai School of Medicine.

IT IS WELL KNOWN that there is a severe shortage of manpower for the delivery of mental health services to children. Although children constitute almost a third of our population, there are only 1,000 child psychiatrists versus 24,000 adult psychiatrists. It is estimated that 2.5–4.5 million children in this country need psychiatric care for emotional problems. In addition, 265,000 children aged 7–17 are seen by the juvenile courts each year on petitions of delinquency or neglect (1). The inadequacy of services for poor and minority children is especially well documented. These children have a higher than normal incidence of serious disorders and often are later referred to child guidance clinics (2–4). Analyses of service utilization data from community mental health centers have indicated that children are underserved in CMHCs (5).

A new method of mental health care delivery for inner-city children, in which a 1.75-mile underground coaxial cable (running along the ducts of the New York City telephone system) links the Mount Sinai School of Medicine with the Wagner Child Health Station in East Harlem, became operational in October 1973. In this paper, we will describe the first two years of this system's operation and discuss its potential for increasing the efficiency of mental health service delivery to high-risk populations where manpower shortages are most acute.

THE WAGNER CHILD HEALTH STATION

The Wagner Child Health Station, a joint program of Mount Sinai Hospital and the New York City Department of Health, serves approximately 1,400 preschool children in health district 17, a triangular area of East Harlem with a predominantly Puerto Rican and black population. The clinic is organized in collaboration with the Department of Community Medicine at the Mount Sinai School of Medicine. Responsibility for primary patient care has gradually been given over to pediatric nurse associates (registered nurses with B.S. degrees who have been trained as pediatric nurse practitioners). The nurse associates were at one time supervised on each case by pediatricians from Mount Sinai, who have gradually removed themselves from the clinic. The nurse associates, who now use treatment protocols and consult with pediatricians via two-way TV when necessary, have become highly autonomous primary care providers. In addition to seeing patients in the clinic, the nurse associates lead a health team that includes three community health workers. These workers have had no formal academic training (most are high school graduates) and are given on-site training by the clinic codirectors, pediatric nurse associates, and pediatricians. Each team alternates a week at the clinic with a week in the community doing outreach work and providing follow-up care.

The mental health component of the clinic was designed to add the psychosocial dimension to the care of each child and his or her family. A psychiatric nurse works at the clinic as part of the health team and serves as liaison to a child psychiatrist at the medical school. The psychiatrist's activities, all conducted using the two-way TV system, have included psychiatric conferences with the nurse associates, training community health workers, psychiatric consultations, and teaching of residents and medical students.

THE PSYCHIATRIC CONFERENCE

A weekly lunch-hour TV conference, during which the child psychiatrist (seated in a studio at the medical school) talks informally to the nurse associates and psychiatric nurse at the clinic, has been the basis of the program. These meetings are informal and vary in content depending on the needs of the nursing staff.

Discussions of problem cases have familiarized the nurse associates with crisis intervention techniques, general principles of child development, and the signs of emotional problems in children. Recommendations by the child psychiatrist are discussed and usually become an integral part of the team's approach to patient care. A frequent topic of the conference is helping the nurse associates decide how best to approach a mother to recommend a television psychiatric consultation. Once the staff's initial resistance to television consultations was overcome by the demonstration of videotaped psychiatric interviews, there was little resistance on the part of the patients. During the period of November 1973 through May 1975, there were 58 staff conferences, which included discussions of 138 problem cases with the child psychiatrist.

Some of the meetings focus on the staff's feelings and resemble a modified form of group therapy. The early meetings reflected the nurse associates' anxieties about assuming the primary responsibility for patient care. Other meetings focused on the frustrations involved in working with families in which there is child abuse, child neglect, parental noncompliance with medical recommendations, and inadequate referral sources. Funding crises, staff departures, and administrative matters are also discussed. It is important to note that a very intense relationship has developed between the nurse associates and the child psychiatrist during these television conferences.

TRAINING OF COMMUNITY HEALTH WORKERS

The child psychiatrist has introduced the community health workers to mental health concepts in two-way TV sessions. Several personal contacts were arranged when the psychiatrist was first hired. These in-person meetings were characterized by suspicion and disinterest on the part of the health workers, who seemed intimidated by the presence of a psychiatrist in contrast to contacts over television. The first TV meeting was designed to clarify the role and functions of a psychiatrist for the health workers. It was arranged after four consultation appointments were not kept so that the health workers could more effectively encourage patients to attend scheduled consultations.

In this meeting, health workers were asked to describe their conceptions of the functions of a psychiatrist. They were shown a videotape of one of their patients being interviewed by the psychiatrist and then were asked about their reactions to the tape. Before they saw the videotape, the health workers perceived the psychiatrist as a judge—someone who confronts people and incarcerates them. They did not see him as concerned or interested in problem solving and thought that only "really crazy" people saw psychiatrists. The videotape dispelled these notions rather dramatically, as was shown in the increased number of patients who attended consultation interviews.

The health workers now attend consultations on their patients unless the patient requests that they not be present. After consultation, they participate in the case planning. They have also asked to have meetings to discuss psychiatric interviews with patients they find difficult.

THE TELEVISION CONSULTATION

A television consultation service of 1 hour a week was started in January 1974, by which time the nurse associates and community health workers had become

advocates of mental health. The TV consultation is a diagnostic interview with an emphasis on early intervention and case planning. During all evaluations, the psychiatrist is in a studio at the medical school and mother and child are with their nurse associate and health worker at the clinic. The nurse or health worker presents the problem before the interview begins. The mother and child are then brought into the room and introduced to the psychiatrist and to any medical students or residents who are observing the interview. The mother is asked if she is willing to have the interview taped for teaching purposes and to allow the students or residents (who are seated off camera) to remain. Only 1 mother has refused the former request; all of them agreed to the latter. The mother and the psychiatrist can see themselves on monitors during the interview. The psychiatric nurse coordinates any referrals for further diagnostic work-up or psychotherapy for the mother or child with Mount Sinai Hospital.

Forty-nine appointments for TV consultations were scheduled between January 1974 and June 1975. All but 2 of these cases were referred by the clinic staff—1 case was referred by an outside agency because the parents refused to talk to a psychiatrist in person but consented to a television interview, and 1 was a self-referral. The proportion of appointments kept (69%) is similar to that of a random sample of consultation appointments at the Mount Sinai Child Psychiatry Clinic (75%). Only 2 of the 15 mothers who did not keep an appointment totally refused to be seen. The others believed their problem had been resolved with the help of the psychiatric nurse or nurse associate, or the problem was situational and resolved spontaneously. Thirty patients were seen in the 34 consultation appointments—19 boys, 10 girls (median age of children=4.1 years), and 1 mother.

The outcome of these evaluations was as follows: resolution of problem as a result of the interview, N=4; further diagnostic study, N=7; recommendation for treatment (for the child or his/her mother or for marital therapy), N=21; and referral to other agencies, N=6 (several interviews resulted in multiple recommendations). Twenty-six of the 30 families involved (86%) accepted the psychiatrist's recommendation and made further appointments. Mothers readily accepted recommendations that they obtain individual therapy, but recommendations for marital therapy were rejected because the husbands would not cooperate. Recommendations for therapy for children were accepted in 66% of the cases. Before the introduction of the TV consultation service, most referrals to the hospital by clinic nurses were refused.

USE OF TELEVISED CONSULTATIONS IN MEDICAL TRAINING

The television consultation service has been integrated into the teaching program of psychiatric residents and fellows in child psychiatry at the Mount Sinai School of Medicine. The fellows, seated off camera, observe the television consultation as part of an orientation course that focuses on interviewing technique, history taking, observation of mother-child interaction, principles of child development, diagnosis, and case management.

After they complete the orientation course, fellows conduct the television consultation interviews while their peers and supervisors observe. Each week a different resident serves as consultant. The interview and videotape are very effective in illustrating interviewing style and pointing out some of the nuances that are often left out of supervision. Child fellows conducted 8 of the 34 interviews from August 1974 through May 1975.

DISCUSSION

This cable-TV link has brought the medical center into contact with preschool children in the inner city. The expertise and facilities of the medical center are now accessible without being intimidating—the children and their families are seen in their own clinic, on their own "turf," with their nurse and health worker present and the psychiatrist and his imagined dangerous powers at a safe distance.

The psychiatrist saves travel time, is able to pursue other interests when patients are unable to keep scheduled appointments, and is at a safe distance from any perceived dangers of the inner city. Linking several child health stations to this system would allow greater utilization of the psychiatrist's time for community walk-in consultations. This arrangement is technically feasible in all major cities that have cable TV.

The use of bidirectional TV has also aided in the development of nurse associates and community health workers to become skilled in case finding and case management. The fact that 28 of 30 cases seen were found within the clinic by the staff contrasts markedly with the usual state of referrals for psychiatry (5) and highlights the efforts of the clinic in early case finding and outreach.

This electronic link has opened the doors of the medical center to patients who would previously have been unable or unwilling to use its facilities. It is our impression that the high degree of acceptance of the psychiatrist's recommendations results from several factors. The patient's first exposure to the psychiatrist occurred in the familiar surroundings of the clinic and was therefore less threatening than an in-person contact at the unfamiliar medical center. In addition, the psychiatric services were well integrated into the clinic services and a good liaison was developed between the clinic staff and hospital personnel.

The psychiatrist's experience with consultation via two-way TV is in agreement with previous reports (6–8). It is difficult to know what, if anything, is lost when contact is by television rather than face-to-face. During the interview, one can observe the nuances of the

child-mother interaction, which are a necessary part of the diagnostic evaluation. The television contacts seem intimate and effective, and all mothers interviewed thus far have responded positively to "being on television." They also seem to gain a sense of heightened self-esteem that is not as noticeable after an in-person consultation. The feeling of being on television and the possible identification with important television and public personalities it may arouse, as well as the gratification of seeing oneself on the monitor, may play a part in this positive reaction.

We cannot make definitive conclusions until more data are collected. However, our experience to date suggests that bidirectional cable TV can be an important new and effective method of mental health care delivery to inner-city children who would often be untreated otherwise.

LETTERS TO THE EDITOR

On Dangerousness and Involuntary Hospitalization

SIR: In his argument against the dangerousness standard for civil commitment ("The Case for Involuntary Hospitalization of the Mentally Ill," May 1976 issue), Paul Chodoff, M.D., speaks of a dilemma confronting psychiatrists who want to help "their" patients who might not meet this legal criterion. It should not be necessary to point out that standards of commitment have virtually nothing to do with control over the treatment of a psychiatrist's patients. Commitment standards determine solely whether a private citizen will become a patient against his will.

Just as a citizen with a heart condition is not subject to compulsory treatment at the hands of altruistic state-employed cardiologists, a citizen suffering from mental illness does not automatically qualify as an involuntary patient of state-employed psychiatrists who are eager to act in his best interests. Among medical doctors, only the community of psychiatrists lobbies for an expanded captive clientele. All other doctors treat those who come for aid and let the rest choose for themselves.

If a rigorous standard of dangerousness is applied to the legal process that turns a citizen into an involuntary patient, it is indeed likely that mental hospitals housing only such patients will, as Dr. Chodoff states, contain "a small population of volatile, highly assaultive, and untreatable patients" (assuming that Dr. Chodoff is not applying all three labels to all who become committed patients under the dangerousness standard). If such is the result, society would benefit from having the community of state-employed psychiatrists focus its treatment efforts on those who are found to be seriously disruptive of society by reason of mental illness. An individual could become "their" patient either by the traditional method of consulting a physician or by the legal process wherein dangerousness as a result of mental illness is found by a court or a jury of peers.

Firmly rooted democratic principles and the inexact nature of the psychiatric art militate against paternalistic and subjective commitment criteria. This is underscored by the grim fact that many of the public facilities in which captive patients will be held and "treated" are professionally unaccredited. For example, in Washington, D.C., where Dr. Chodoff practices, there are currently no accredited public facilities for involuntary patients.

HARRY J. FULTON, ESQ.
Washington, D.C.

SIR: Dr. Chodoff is on target when he points out that dangerousness as the sole criterion for involuntary hospitalization is a trap for psychiatry. However, he shows an ignorance of constitutional law when he states that "involuntary commitment on these grounds becomes a form of preventive detention and makes the psychiatrist a kind of glorified policeman." Dr. Chodoff should know that no policeman in this country has the right to detain anyone in order to prevent the commission of a crime or dangerous act. Of course, preventive detention is standard operating procedure in totalitarian countries. Thus a psychiatrist practicing preventive detention is not merely augmenting the duly constituted police power of the state but actually subverting constitutional guarantees.

Dr. Chodoff is much less convincing in his defense of involuntary hospitalization on the grounds that an individual is mentally ill, in need of treatment, and lacking the judgment to know what is in his/her best interests. Just because physicians have been reminded of the need for safeguards by the current stringent requirements for involuntary hospitalization in some states, there is little reason to believe that if the requirements were made less strict (as Dr. Chodoff feels they should be) "chastened" psychiatrists would refrain from abusing their power. The elementary historical fact is that discretionary power leads inevitably to abuses of that power. The criminal justice system has recognized this fact and is in the process of reducing judicial discretion in sentencing, probation, and parole. The recently disclosed abuses of power by the FBI and CIA should have taught us the dangers of police powers that are not subject to the usual consititutional protections. Parens patriae requires the bestowing of wide, poorly defined, discretionary powers on physicians, who although they may mean well, will in time abuse these powers.

IRWIN N. HASSENFELD, M.D.
Albany, N.Y.

Dr. Chodoff Replies

SIR: I am pleased that Dr. Hassenfeld has placed himself in the ranks of those psychiatrists who are coming to see that dangerousness as a sole criterion for involuntary hospitalization becomes a trap for psychiatry. He is not entirely correct when he states that preventive detention does not exist in legal form in the United States. In fact, there is a preventive detention statute in the District of Columbia, although it has not yet been invoked, and I have been told that a similar statute also exists in Alaska. However, I want to make it clear that I am not an advocate of preventive detention. I agree that under any circumstances it is a practice of exceedingly questionable legal and ethical validity and that its acceptance constitutes a step toward a totalitarian state. It is for this reason that I point out the untenable position psychiatrists find themselves in when the constraints of the dangerousness criterion force them into the role of agents of preventive detention in order to bring about involuntary psychiatric hospitalization.

The other point made by Dr. Hassenfeld is the same as that put forth in Mr. Fulton's letter, that psychiatrists cannot be trusted to make medical judgments that would have the effect of depriving the patient of his liberty against his will. Both writers feel that the abuses which occur when psychiatrists are invested with this power are intolerable. In my paper, I acknowledged that abuses may occur. However, they

are unlikely to have much currency if the patient is protected by judicial review, legal representation, the right of appeal to a jury, and the abolishment of indeterminate commitment, all of which I advocate.

What Dr. Hassenfeld and Mr. Fulton fail to consider are the abuses, injustices, and wrongs that can and do take place when sick people desperately requiring treatment and unable to exert their judgment to seek or accept it are prevented from getting such treatment simply because they are not "dangerous." It may be that patients need to be protected not only against "the community of psychiatrists lobbying for an expanded captive clientele" but also against those who may be using liberty as a rallying cry that conceals equally grave and possibly more irreparable abuses.

Finally, I regret the tone of Mr. Fulton's letter. The subject discussed in my paper is not appropriately dealt with in a polemical manner. It should be discussed with goodwill and with a recognition that it is not susceptible of simplistic solutions. Mr. Fulton appears to want to place it in the domain of drama—the struggle of a right that he espouses against a wrong promulgated by certain psychiatrists. However, the question of when to hospitalize people against their will to try to restore them to health or save their lives is not drama; it is more akin to Greek tragedy—the conflict of one right against another right.

PAUL CHODOFF, M.D.
Washington, D.C.

Somnambulism and Bedtime Medication

SIR: I was interested in "Pavor Nocturnus: A Complication of Single Daily Tricyclic or Neuroleptic Dosage" by Abraham Flemenbaum, M.D. (May 1976 issue) because I have long been impressed by the fact that patients taking neuroleptics, antidepressants, and even antihistamines at bedtime often complain of "dreaming too much" and frequently report frightening dreams. I was particularly interested in Dr. Flemenbaum's observation that one of the patients he described had had an episode of somnambulism for the first time in her life while taking a single bedtime dose of medication. Some years ago I observed within one year four cases of somnambulism apparently precipitated by bedtime medication.

The four women were outpatients ranging in age from 29 to 54. Some of the patients were taking neuroleptics during the day; at bedtime they received either a higher dose of neuroleptics or hypnotics. The neuroleptics were chlorprothixene, perphenazine, and thioridazine. The hypnotics were methaqualone alone (one patient) and a compound containing methaqualone and diphenhydramine hydrochloride (two patients). One of the patients who was taking the combination drug was also taking a compound containing amylobarbitone sodium and quinalbarbitone sodium. The fourth patient was taking chlorprothixene at bedtime. The episodes of somnambulism were typical, with sleepwalking and other activities followed by amnesia. In one patient (a 49-year-old woman with chronic anxiety), sleepwalking occurred three times and she woke up during each episode. During one episode, her husband stopped her when she was opening the door. At that moment, she woke up and then remembered that she had dreamed the door bell was ringing.

The episodes of somnambulism disappeared when the hypnotics containing methaqualone were discontinued or the bedtime dose of chlorprothixene was reduced. Follow-up ranged from 2 months to 1 year, with no recurrence of somnambulism.

I suspect that there may exist more unreported cases of sleep disorders related to bedtime medication. Studies like the one by Dr. Flemenbaum may help to indicate whether this phenomenon is more common than we have thought.

LUIS HUAPAYA, M.D.
Montreal, Que., Canada

In Defense of the Boards

SIR: Having been involved in teaching psychiatry to medical students, I detected some similarities between the noble attempts made by my students to justify inadequate performance in the classroom and some of the issues raised by Martin R. Lipp, M.D., in "Experiences of Psychiatry Board Exam Casualties: A Survey Report" (March 1976 issue).

By way of an anecdote, on one occasion a fourth-year medical student was unable to discuss a basic concept in psychiatry. After much hemming and hawing, another student came to his rescue and said, to my amazement, "He's not very verbal." These words came back to me as I read Dr. Lipp's attempts to gloss over the importance of oral examinations in psychiatry.

Dr. Lipp has not paid attention to the fact that many people do pass the Boards. The essential difference in outcome may have much to do with preparation. The article makes much of the high failure rate in the examination. However, as shown in the *Journal of the American Medical Association* State Board Numbers, high failure rates were customary for years in state licensure exams. Since all of the "casualties" had licenses, it would have been interesting to see how they compared the two exams.

It would be unfortunate to encourage "grade inflation" in the qualifying professional exams. The universities now have the problem of sorting out essentially meaningless numerical hyperboles that used to have some significance. Let us spare our patients the trouble of turning to Ralph Nader to find out who is qualified in psychiatry!

ALAN E. RAINESS, M.D.
Silver Spring, Md.

Dr. Lipp Responds

SIR: Dr. Rainess emphasizes the importance of preparation for passing oral Board exams. I agree with him. However, there is a kind of predicate logic here that needs to be identified. Just because knowledge and rigorous preparation are useful in taking the Boards does not mean that the Boards therefore provide an accurate means of assessing these qualities. Oral exams are complex social situations in which the personalities and situation-specific behavior of candidate, patient, and examiner may play as great a role as knowledge.

In fact, all candidates taking the orals have already demonstrated that they have an acceptable fund of current knowledge, as measured by the written exams, which are a prerequisite for taking the orals. One cannot say the same thing for the examiners, who may not have been required to formally document the accuracy and breadth of their knowledge for decades.

The important point is that the exams simply have no de-

monstrable reliability and validity in terms of identifying clinical competence. I challenge Dr. Rainess, or anyone, to provide evidence to the contrary. Anecdotes can be amusing, but they provide a slippery foundation for public policy.

In the absence of such evidence, we must recognize that we are subjecting our colleagues and ourselves to what is little more than a hazing process—a harmless rite of passage for those who are successful, but a cruel gauntlet for those who are not.

Is an examination process that is of no proven relevance to excellence of patient care worth the brutal costs to our profession? And worth it to whom?

I think the onus is on the American Board of Psychiatry and Neurology to demonstrate the meaningfulness of its procedures or find a new means of certifying professional competence.

MARTIN R. LIPP, M.D.
San Francisco, Calif.

Lithium in Schizophrenia

SIR: I would like to comment on "A Placebo-Controlled Study of Lithium Combined with Neuroleptics in Chronic Schizophrenic Patients" by Joyce G. Small, M.D., and associates (December 1975 issue). During the past year, I have treated four chronic schizophrenic patients who had not responded favorably to neuroleptics with a combined neuroleptic and lithium therapy. I have found a varying degree of success; all patients are doing better and their symptoms are better controlled on this regime than they were by neuroleptics alone. I feel, as do Dr. Small and associates, that lithium may have a definite place in the treatment of chronic schizophrenics who do not respond well to neuroleptics alone. There is a need for further investigation in this area.

A. TAHERI, M.D.
Ellicott City, Md.

In Defense of a Second Edition

SIR: I have never complained about a book review, but I do take exception to Dr. Benjamin J. Sadock's review of the second edition of *The Theory and Practice of Group Psychotherapy* by Irvin D. Yalom (May 1976 issue). I reread my own review of the book and began to wonder whether Dr. Sadock and I had read the same volume. My report read,

> Dr. Yalom has written a minor masterpiece. He creates clarity with plain, simple English. At the same time he seems to have included every significant article in the bibliography and every point of view in the text. Usually a writer has to sacrifice either detail or clarity. Yalom manages to sacrifice neither. Most importantly—at least to this reader—was the author's careful separation of clinical opinion, his own and others', from marginally substantiated and reasonably substantial experimental data. This careful separation of opinion from established or moderately established experimental data is refreshing and rare.

While any book can be improved, Dr. Yalom's work is the most complete review of the theory and practice of group psychotherapy published to date. The only way I can account for the negative review is that Dr. Yalom may have stepped on some sensitive psychoanalytic toes. In all fairness, are psychoanalysts any less apt to express their "personal views" and then mistake their ideas for facts?

FRANK KLINE, M.D.
Los Angeles, Calif.

SIR: It seems to me that Dr. Sadock was an unfortunate choice to review the second edition of Dr. Yalom's book on group therapy because he has recently edited a book on group psychotherapy himself. While he is an eminent and knowledgeable authority and undoubtedly did his utmost to be objective, I question whether and to what extent this is possible. It seems to me that in the interests of objectivity and the appearance of objectivity, book reviewers should not have participated in competing works. Since the Editor of the *Journal* cannot be expected to keep track of the authors of all books, the letter that is sent to potential reviewers should request them to disqualify themselves if they have written or are preparing a competing book.

HENRY GRUNEBAUM, M.D.
Boston, Mass.

Questioning a Diagnosis

SIR: The article "Mania and Bromism: A Case Report and a Look to the Future" by A. Joseph Sayed, M.D. (February 1976 issue) raises a number of questions. First, the initial serum bromide level (32.5 mg/100 ml), while elevated, is well below the generally accepted lower limits of toxicity. "Bromide intoxication should be considered as a possible cause of any unexplained mental or neurological symptoms occurring when the serum bromide level exceeds 9 mEq per liter (72 mg/100 ml)" (1). This suggests that bromism is a coincidental rather than a causal finding.

Next, given a biologic half-life of 12 days (2), it is surprising that "a serum specimen drawn 6 days later was negative for bromide." The article did not mention any efforts to hasten the elimination of bromide, and in the absence of such measures one must question either the initial or 6-day value.

The source of the bromide remained obscure, but the author speculated that a bromide-containing antacid was the culprit. I am not aware—nor is the Drug Information Center at the University of Wisconsin-Madison Center for Health Sciences—of a bromide-containing antacid, but if such a preparation is available, it represents a potential hazard and deserves identification.

While it is difficult to disagree with the author's conclusion that manic behavior may occur secondary to bromism, I find little substance in the case report to justify this conclusion. The even more ethereal suggestion that bromide may be linked in a significant way to manic-depressive illness is an interesting speculation but, again, is not supported by the case described.

2. Söremark R: The biological half-life of bromide ions in human blood. Acta Physiol Scand 50:119–123, 1960

JAMES W. JEFFERSON, M.D.
Madison, Wis.

SIR: I noted that the serum bromide level of the patient Dr. Sayed described was 32.5 mg/ml and that the author considered this toxic and stated "normal=less than 1.5 mg/100 ml." I hope that this was a typographical error, as the toxic level of bromide is much higher than that indicated by the author.

MAHMOUD ABBAS, M.D.
Baltimore, Md.

Dr. Sayed Replies

SIR: Dr. Jefferson made three points in his letter. As the first is similar to that made by Dr. Abbas, I will address it later. Concerning the second point, I have no explanation for the rapid drop in the patient's bromide level. There was no attempt to lower the level.

Dr. Jefferson's third point is important. The bromide-containing antacid I referred to is Bromo-Seltzer (Warner-Lambert). The company had removed the bromide salt from the product by August 1973; the patient was hospitalized in September of 1974. I thought it was possible that the product might still be on the shelves in some stores, or it could have been purchased previously. At the present time, the availability of bromide-containing Bromo-Seltzer is negligible, but bromide is still available in many other compounds. For this reason, I felt the case report would be important in future considerations of both patient evaluation and research in affective illnesses.

In response to Dr. Abbas, the bromide level printed in my article is correct. However, Dr. Abbas has not summarized my conclusions correctly. What I said was, "The patient described here exhibited classical features of mania but did not show signs of bromide intoxication or delirium, although his serum bromide level was abnormally high." The purpose of the case report was to describe a patient who showed no evidence of neurological toxicity but did have an abnormal change in mental functioning that has not been previously reported in association with bromide ingestion. In fact, the bromide level was not in the toxic range, but was elevated considerably above the normal range.

A. JOSEPH SAYED, M.D.
Cincinnati, Ohio

Two Problem-Oriented Letters

SIR: I read with interest "The Use of Problem-Oriented Medical Records in Community Mental Health Centers" by Garry M. Vickar, M.D., and Marijan Herjanic, M.D. (March 1976 issue). I am a member of a subcommittee of the Department of Psychiatry at Thistletown Regional Center for Children, Rexdale, Ontario, which examined the use of a problem-oriented, goal-oriented record (POR-GOR). We found several problems that I would like to describe, along with possible solutions.

1. Quality of patient care—there is a lack of evidence that the POR-GOR improves the quality of care. In order to determine this, it would be necessary to do a comparative study of treatment outcome using traditional and problem-oriented approaches.

2. Defining the data base. The emphasis seems to be on collecting the minimum amount of information necessary to formulate problems, which could exclude normative or negative information and lead to an insufficient data base. Clear standards should be set for the services of a center and the emphasis should be on gaining the maximum possible information rather than the minimum necessary.

3. Diagnosis and formulation. This information should be included in every record. There tends to be an emphasis on formulation of problems rather than a holistic view of the case. This may have implications for treatment and training.

4. Problem definition. Guidelines should be established for each service area. There should be input from several disciplines in order to avoid a lengthy and perhaps piecemeal treatment approach.

5. Implementation. If problem-oriented systems are to be used, extensive discussion and education are necessary to avoid mere substitution of one ritual for another.

6. Deficiencies in the traditional psychiatric record. A clinical records committee should label the deficiencies of the traditional system; this would provide a basis for discussion and facilitate acceptance of the change to a problem-oriented format.

7. Progress notes. One needs to refer constantly to the problems list. This requires the full record for one to write the progress note. An alternative to referring to problems other than by numbers needs to be devised.

In conclusion, I would like to say that a problem/goal-oriented record system should not be introduced in haste at any center until these difficulties can be resolved.

P.K. JOHN, M.D.
Rexdale, Ont., Canada

SIR: I was very pleased to see the article by Edward H. Liston, M.D., on "Use of the Problem-Oriented Medical Record in Psychiatry: A Survey of University-Based Residency Training Programs" (June 1976 issue). Although the data were collected in November 1974, I think it is still very important that psychiatrists see the degree of acceptance of the problem-oriented system at that time. Despite the acceptance and what I suspect is increased utilization of the problem-oriented system in psychiatry since November 1974, I believe it is important that a healthy skepticism about utility lead to more study and research on the system. The APA Task Force on Problem-Oriented Systems will soon report its belief that current knowledge about the problem-oriented system is insufficient to warrant recommending its widespread utilization or the mandating of the system for such purposes as third-party reimbursement, peer review, audit, or other accountability studies.

The point raised by Dr. Liston concerning the importance of continuing education, audit, and correctional feedback in order to be satisfied with implementation of the problem-oriented system is a very important one. Currently, Fort Logan Mental Health Center is implementing the problem-oriented system and has a comprehensive plan both for the initial stages and continuing emphasis on the system.

The criticism that the system seems less relevant or applicable to psychoanalytic approaches to treatment is one that is widespread. In almost all cases my experience suggests that those who make this criticism have no essential grasp of the problem-oriented system. Useful criticism, like useful

teaching, can best be done from a position of experience. In the Department of Psychiatry at the University of Colorado, we are attempting to find applicability of the problem-oriented system within a psychoanalytic framework. Early efforts seem encouraging, especially those from the outpatient clinic under the direction of Dr. George Mizner. We hope to report these efforts in the near future.

RICHARD L. GRANT, M.D.
Denver, Colo.

BOOK REVIEWS

The Foundations of Psychiatry. American Handbook of Psychiatry, 2nd ed., Vol. I, *edited by Silvano Arieti; Silvano Arieti, editor-in-chief. New York, N.Y., Basic Books, 1974, 1,215 pp., $29.50.*

Child and Adolescent Psychiatry, Sociocultural and Community Psychiatry. American Handbook of Psychiatry, 2nd ed., Vol. II, *edited by Gerald Caplan; Silvano Arieti, editor-in-chief. New York, N.Y., Basic Books, 1974, 836 pp., $24.50.*

Adult Clinical Psychiatry. American Handbook of Psychiatry, 2nd ed., Vol. III, *edited by Silvano Arieti and Eugene B. Brody; Silvano Arieti, editor-in-chief. New York, N.Y., Basic Books, 1974, 860 pp., $24.50.*

Organic Disorders and Psychosomatic Medicine. American Handbook of Psychiatry, 2nd ed., Vol. IV, *edited by Morton F. Reiser; Silvano Arieti, editor-in-chief. New York, N.Y., Basic Books, 1975, 922 pp., $32.50.*

Treatment. American Handbook of Psychiatry, 2nd ed., Vol. V, *edited by Daniel X. Freedman and Jarl E. Dyrud; Silvano Arieti, editor-in-chief. New York, N.Y., Basic Books, 1975, 954 pp., $32.50.*

New Psychiatric Frontiers. American Handbook of Psychiatry, 2nd ed., Vol. VI, *edited by David A. Hamburg and H. Keith H. Brodie; Silvano Arieti, editor-in-chief. New York, N.Y., Basic Books, 1975, 1,022 pp., $32.50.*

How does one go about reviewing an encyclopedic offering of six volumes that practically cover the whole of modern psychiatry, with a history of the discipline and some prognostications for the future included for good measure? The answer is, of course, one cannot; yet it must be done, even though the effort be clumsy, because the task is before us and the time for the appearance of the full set of these volumes is propitious.

Despite all of the pressures and hazards of psychiatric practice today and despite the idle croaking of the batrachians about us, the profession is growing at an accelerated pace and is being enriched by the contributions of various scientific disciplines. Having gone through its growing pains, the specialty of psychiatry is taking its place with its sister medical disciplines; however, to tell the truth, no medical discipline is having an easy time of it these days.

The six volumes of Dr. Arieti's *Handbook* are testimony to psychiatry's accomplishments, to the skill of the editor-in-chief, and to the faith and cooperation of his colleagues and his publisher. Assembling all of this material was in itself a prodigious task; Arieti was fortunate in the selection of both his authors and his fellow editors. Because it is almost impossible to do justice to this work in a journal review, I will say only a word or two about each volume and trust the wisdom of potential readers for the rest.

In general the presentations seem to be inclusive and of a high order. The authors of most of the presentations will be recognized as authorities. Some of the younger authors hold promise for the future. All in all it is probably the most comprehensive effort yet to appear in the literature of modern psychiatry; undoubtedly it will be used as a reference work by clinicians, teachers, researchers, and students in various fields for a long time to come.

The first volume assesses the basic ideas of the psychiatric disciplines. Genetics, the family, and personality are all considered, as are the concepts of normality and maturity. In addition, there are excellent discussions of the life cycle and the various psychiatric schools of thought as well as contributions from related fields. Psychiatric nomenclature is also outlined in this volume.

The second volume covers child and adolescent psychiatry as well as sociocultural and community psychiatry. The names Lourie, Ackerman, Goldfarb, Eisenberg, Anthony, and Raquel Cohen give evidence of the high quality one can expect in these articles. A discussion of the federal government's organization for human services and its implications for health planning is offered by the knowledgeable authors Brown and Isbister. All of this is informative, and much of it hints at what the future holds.

The third volume is concerned with adult clinical psychiatry, focusing on specific neurotic and character disordered behavior and syndromes associated with action directed against the environment. Here again the names of the contributors are impressive, and all of the various psychological deviations are discussed. Addictive behavior, drug addictions, and the use of psychotomimetic and related consciousness-altering drugs come in for their share of attention, as do functional psychoses.

The fourth volume contains some excellent discussions by top-notch observers, e.g., among others, Stunkard on obesity, Hilde Bruch on anorexia nervosa, and Jack Mendelson and Nancy Mello on alcoholism.

The fifth volume is concerned with treatment. After an excellent introduction by the editors, Jerome Frank discusses the psychosocial therapies, and Blos and Finch consider psychotherapy in children. Somatic therapies, management and care of patients, various aspects of legal medicine, and a consideration of psychiatry for the 1970s are all given their due; the latest information about each of these areas is presented.

The sixth volume includes sections titled Basic Approaches to the Understanding of Human Behavior, The Development of Behavior Frontiers, Psychopharmacology, New Directions in Treatment and Care, and The Social Context of Psychiatry.

As already noted, one cannot do justice to this encyclopedia in a review; in fact, one feels like a child in a candy store—he doesn't quite know what to select because he really wants it all. It is obvious that there are seeds for a lifetime of study in these volumes. They belong on every library shelf as well as in the libraries of those physicians who can see their way clear to obtain them. The work is comprehensive, authoritative, and, in general, excellent.

F.J.B.

A Prince of Our Disorder: The Life of T.E. Lawrence, *by John E. Mack. Boston, Mass., Little, Brown and Co., 1976, 537 pp., $15.00.*

Written by one of the most capable psychiatrists in the Boston area, this book is an extraordinary accomplishment. It is both a biography of T.E. Lawrence and a thorough analysis of the uncommon series of personal tragedies experienced by the subject, who became famous in large part because of Lowell Thomas' dramatic reporting of his involvement in Middle East affairs during and after World War I. Anyone who reads and studies Lawrence's *Seven Pillars of Wisdom* (1) and this biography and character analysis will know almost as much about Lawrence as anyone needs to know, but the task requires keen attention.

The author worked on this book for many years; he consulted with an extraordinarily large group of persons in this country and abroad who have shared his interest in Lawrence. Not only has he done extensive research of all of the published material relating to his subject, he has interviewed at length dozens of persons who knew Lawrence personally. Not surprisingly, Lawrence's psychological constitution receives very intensive study. The result is a character analysis of such depth and accuracy that it will seldom be challenged.

This book is strongly recommended to anyone interested in Lawrence as well as to all who are fascinated by accounts of how serious personal handicaps can be transformed into constructive action.

Schizophrenia: A Multinational Study. A Summary of the Initial Evaluation Phase of the International Pilot Study of Schizophrenia. Public Health Papers 63, *by the World Health Organization. Geneva, Switzerland, WHO (New York, N.Y., Q Corp., distributor), 1975, 150 pp., 56 Swiss francs (paper).*

Under the auspices of the World Health Organization, a group of experts met in 1959 to review the existing data on the epidemiology of mental disorders. They concluded that there was considerable need for reliable and valid data on the incidence and prevalence rates of these conditions. Over a period of years and with a series of consultations the international pilot study of schizophrenia (IPSS) gradually emerged. It set as a very high priority the goal of carrying out epidemiological research in a cross-cultural setting. In 1966 the formal study began. It resulted in a report that was published in 1974 (1). Because that 427-page publication achieved only limited visibility, it is a pleasure to welcome *Schizophrenia: A Multinational Study*, an authorized abridged version that will be readily available to the public as an individual number in the *Public Health Papers* series.

The obstacles presented to the research team were indeed formidable. The study was conducted in nine countries and involved over 1,200 patients. Because nine countries reflected very different scientific and cultural traditions, it was a very difficult task to create circumstances in which the researchers could collaborate on, let alone conduct, the project. One of the potentially richest products of the IPSS is the development of functional collaborative relationships.

The project exerted a great deal of effort in the development of clinically reliable research instruments. These instruments were developed and applied across the nine cultures involved in the study. It is a very important finding that schizophrenia can be reliably identified despite striking cultural differences. Obviously, cross-cultural reliability does not address the question of validity; nevertheless, it does refute the often stated claims that the diagnosis of schizophrenia cannot be made reliably and that it is not stable in the face of cultural differences.

Perhaps the most important finding of the IPSS is the demonstration that schizophrenia in the nine countries is essentially similar. Patients could be identified in each culture who were indistinguishable from one another. This finding obviously does not address the issue of the universality of schizophrenia, but it does a great deal to demonstrate the basic similarity of the syndrome in the cultures studied.

This small pamphlet summarizes succinctly the essential findings of the international pilot study of schizophrenia. It is of general interest to the practicing clinician because of its emphasis on such practical problems as diagnosis. This abbreviated version of the initial report presents the basic results, but it would be wiser, in my judgment, for the schizophrenia specialist to read the more complete edition.

Current Psychiatric Therapies, Vol. 15—1975, *edited by Jules H. Masserman, M.D. New York, NY, Grune & Stratton (Harcourt Brace Jovanovich), 1975, 300 pp., $25.00.*

This most recent edition of a deservedly popular series is highly practical and less discursive than some of the previous editions have been. The philosophical presentation is confined to the scholarly and—finally—optimistic presidential address presented by the editor to the Fifth International Congress of Social Psychiatry, which appears in this volume as the leadoff article. It may be worth noting that Dr. Masserman's preoccupation with Ur-needs and Ur-essentials has flowered into hopeful attention to man's Ur-aspirations.

The remainder of the book follows the usual format—division into sections devoted to Child and Adolescent, Adult Psychotherapies, Psychophysiologic Therapies, Family and Group Therapies, Crisis and Community Therapy, and Institutional Therapies. In each there are attempts to reevaluate or suitably modify traditional therapies or to find new therapies or new uses for older ones, and almost without exception there are practical notes in each article that should be invaluable to students and practitioners.

Obviously, it would be impossible to do much more than list the 36 articles that have been contributed to this book; however, without attempting to make any judgments except those based on my own interests, a few comments might be in order. For example, it is refreshing to have a report on a clinic for hippies in Sudbury, Northern Ontario, that winds up with a rather sorrowful statement amounting to, "It sim-

ply didn't work." Perhaps we should have more frank statements about our failures in such enterprises.

In an article on psychiatric treatment modalities in burn patients, Jorgensen and Brophy express appropriate concern over the staff/patient conflicts that arise around the issue of the dangers of "excessive narcotics." Because freedom from pain is usually a treatment modality that is always available, it is sad that in their attempt to guard their patients against excesses, doctors and nurses inadvertently may produce unnecessary apprehension or even discomfort. The reason given for their vigilance by medical personnel is that there is always the possibility of iatrogenic addiction, but I wonder how often this actually occurs.

The final two sections of this book are devoted to Crisis and Community Therapy and Institutional Therapies. These contain some interesting suggestions for making better use of certain treatment modalities within institutions and various community-oriented programs outside institutions in order to facilitate the "dehospitalization" of patients. It is perhaps fitting that Barton's paper on this topic is the closing one in the book.

In summary, this volume offers in condensed form a very down-to-earth exposition of many of the present-day modalities and some interesting and, one hopes, useful innovations. The material is well organized and instructive.

Freud: The Fusion of Science and Humanism. The Intellectual History of Psychoanalysis. Psychological Issues Monograph 34/35, *edited by John E. Gedo and George H. Pollock. New York, N.Y., International Universities Press, 1976, 438 pp., $12.50 (paper).*

The intention of this collection of 16 papers is to review the intellectual history of psychoanalysis and to reemphasize Freud's aim of understanding man's inner life through his view of humanist introspection. Fifteen of these papers have been published elsewhere in various psychoanalytic periodicals. They are all the work of members of the Chicago Psychoanalytic Institute.

The papers are divided into five groups: Background, Precursors, The Creation of Psychoanalysis, Freud's Mature Working Methods, and Freud and the Psychoanalytic Community.

The first group depicts the history of introspective psychology from its inception during the Renaissance through its relegation to humanist philosophy as science became more materialistic. The papers in this group also show the cultural patterns of the nineteenth century in which Freud grew as well as examining the written productions of Freud's adolescence.

The second group, Precursors, recounts the antecedent work of Charcot and Josef Breuer as well as the case of Anna O, Breuer's patient with whom the cathartic method of psychotherapy began.

The third group, The Creation of Psychoanalysis, delineates the difference in creative techniques in psychoanalysis between those of Breuer and Freud. With his mixture of scientific caution and public candor, Freud finally alienated himself from the medical community and returned to his introspective methods.

The fourth group, Freud's Mature Working Methods, describes Freud's formation and subsequent modification of several of the psychoanalytic hypotheses leading to the hypothesis of the universality of the Oedipus conflict. The authors show the progress of Freud's thought in modifying hypotheses through his introspective methods derived from his own self-analysis.

The last group examines Freud's influence on his contemporaries (with special attention to Ferenczi) and on his followers, who have special problems in examining the life and work of a man with whom they have strong identifications.

The papers are all well written and relatively clear for this genre. Considering that there are two editors and nine authors and that the papers were written over a period of more than 15 years, there is remarkable flow and coherence. The book stands as a scholarly work, both in showing the development of Freud's thinking and as an adjunct to more purely historical accounts, such as Jones's biography of Freud (1) and Schur's *Freud: Living and Dying* (2).

Sexual Assault: The Victim and the Rapist, *edited by Marcia J. Walker and Stanley L. Brodsky. Lexington, Mass., Lexington Books (D.C. Heath and Co.), 1976, 175 pp., $15.00.*

As the incidence of reported rape increases, so does the literature on the topic. Walker and Brodsky have edited this book to achieve three goals: 1) to raise the complex issues of cause and prevention of rape and offer some preliminary answers, 2) to show the range of current developments in dealing with the victim and understanding rape, and 3) to offer a book that is both readable and scientifically sound.

Without any question the editors have achieved the first two goals. However, the chapters, which are based on papers presented at the 1975 conference titled Rape: Research, Action, Prevention, vary from the more readable, often action-approach focus to a more scientific consideration of the problem. Perhaps this unevenness was inevitable given the conference's focuses.

Not every chapter presents new ideas or new material; nevertheless, those working with rape victims and/or rapists and those attempting to establish prevention programs will find it helpful to read this book. Those concerned more generally with aspects of mental health could benefit as well.

The issues dealt with fall into several categories: 1) assumptions regarding the nature of rape and how these assumptions relate to prevention strategies, 2) consequences for victims of rape, 3) prevention of rape, 4) rape and race, 5) legal and social definitions of rape, and 6) criminal justice agencies.

Lynn Curtis, a research associate at the Bureau of Social Science Research in Washington, D.C., makes a significant contribution to the literature on rape. In his chapter "Present and Future Measures of Victimization in Forcible Rape" he discusses the contradictory nature of social statistical indicators of rape victimization and the role that police reporting bias possibly plays in this situation. In another chapter, "Rape, Race, and Culture," Curtis explores the meaning of

rape in black communities. Although according to Curtis a formal theory of rape among poor blacks would be premature, this material is set forth to provoke debate in order to stimulate the emergence of theory.

The research reported by Stanley Brodsky on prevention of rape should be read by all women as well as people working specifically to prevent rape. This study was a preliminary effort to study the verbal interactions between the potential victim and an assailant with a view toward preventing sexual assault. The author indicates that the development of a grid that presents patterns of attacker behavior and victim responses, although only a beginning, remains the next step toward prevention.

All in all this book adds to the rapidly emerging knowledge on sexual assault. The editors are to be commended for producing it and for including an index.

San Francisco, Calif.

The Psychoanalytic Study of the Child, Vol. 29, *edited by Ruth S. Eissler, Anna Freud, Marianne Kris, and Albert J. Solnit. New Haven, Conn., Yale University Press, 1974, 528 pp., $15.00.*

The high level of excellence of this annual publication has long been a tradition, and volume 29 does not detract from the merited reputation the series has achieved. It follows the established format of four sections titled Contributions to Psychoanalytic Theory, Aspects of Normal and Pathological Development, Clinical Contributions, and Applications of Psychoanalysis. The only departure from the usual format is a brief initial section honoring the memory of Berta Bornstein, who died in 1971. This section, which is made up of four short papers originally presented at the Memorial Meeting for Berta Bornstein at the New York Psychoanalytic Society and Institute on October 16, 1973, closes with a eulogy by Peter Blos and a bibliography of Berta Bornstein's writings.

Among the contributors to this volume are many well-known psychoanalysts: Margaret Mahler, Samuel Ritvo, Hans Loewald, Robert Bak, Lawrence Kubie, Jules Glenn, Otto Isakower, and Maurits Katan, to name a few.

The short paper by Mahler is a lucid and succinct account of "The Psychological Birth of the Human Infant," which Mahler sees as distinct from the "biological, actual birth experience." This view is predicated on careful observation and plausible reasoning, attributes with which readers of Mahler's works are certainly familiar.

Ritvo's paper on the infantile neurosis, discussed in this volume by Loewald, is a nicely organized presentation of the infantile neurosis from the standpoints of past and present psychoanalytic formulations, implications for diagnosis and technique, and the relationship of childhood to adult neurosis. Robert Bak's contribution, "Distortions of the Concept of Fetishism," is a welcome and lucid attempt to dispel some of the confusion involved in the use of the concepts of transitional object, infantile fetish, and childhood and adult fetishism.

Kubie returns to a favorite topic in his brief paper "Impairment of the Freedom To Change with the Acquisition of the Symbolic Process." In the section on Applications of Psychoanalysis, Jules Glenn deals in an interesting fashion with "The Adoption Theme in Albee's Plays," highlighting the neglect of this theme in the psychoanalytic literature. Katan's paper, "The Development of the Influencing Apparatus," deals with a relatively overlooked element in Freud's paper "A Case of Paranoia Running Counter to the Psychoanalytic Theory of the Disease" (1).

Of special interest is Isakower's paper, "Self-Observation, Self-Experimentation, and Creative Vision." This paper, which was read at the New York Psychoanalytic Society on February 27, 1945, is here published for the first time.

Houston, Tex.

Emotional Problems of Adolescents, 3rd ed., *by J. Roswell Gallagher, M.D., and Herbert I. Harris, M.D. New York, N.Y., Oxford University Press, 1976, 199 pp., $8.95.*

Coauthored by a pediatrician and a psychiatrist, this book is written primarily for nonmedical personnel, but professionals could benefit by reading it.

The various chapters deal with the impact of adults on adolescents, sexuality, achieving independence, and ways to help the youngster. Anxiety states and psychosomatic disorders as well as severe disorders are described. Further, the book addresses itself to antisocial behavior, including the abuse of alcohol and other drugs. There is an extremely interesting chapter titled "The Pitfalls of Testing." "Scholastic Failure" follows, and the last chapter is titled "What Price Success?"

Perhaps the most important things stressed by the authors throughout the book are the changeability of the adolescent, his or her need to grow and leave the dependency of childhood, and the necessity for the adult to treat the adolescent as an individual rather than reenact his or her own childhood through the teenager.

This is a relatively short book, but it is filled with a great deal of practical advice and written by authors who obviously understand teenagers. They recognize teenagers' changeability and the transient problems they may develop; at the same time the authors are alert to warnings of more serious difficulties that may arise during this period of life. The book is written in a nontechnical manner, which should be acceptable and useful (as the authors hope) to such people as ministers, camp counselors, and schoolteachers. It seems to me that it would also be useful to medical students and students in allied health and mental health disciplines. It is well written, concise, and quite practical.

STUART M. FINCH, M.D.
Tucson, Ariz.

Power: The Inner Experience, *by David C. McClelland. New York, N.Y., Irvington Publishers (Halsted Press, John Wiley & Sons, distributor), 1975, 421 pp., $15.95.*

This timely book contains much of interest to those who work with people and their human motivations, to social sci-

entists who have a concern for the application of research findings, and to those who puzzle over why the nations of the world behave in seemingly irrational ways. It brings together the work of a number of researchers over a considerable time period and is, in some aspects, worldwide in scope. Even so, its lucid style makes the tabular summaries of findings quite comprehensible and gives the reader the satisfying feeling that he or she can see the bases for the interpretations offered. For the most part, it is exciting to read. A number of the instruments used and some additional tables are included in the appendix, which is followed by an extensive bibliography.

Starting with male American subjects, McClelland discusses ways of experiencing power, means of measuring the power motive, and how the power motive changes its expression at different stages of maturity. American females are examined next; note is made of the different means by which the power motive must be measured and the rather different modes of expression between men and women—particularly in the idea that giving may serve as fulfillment of the power need. The focus then shifts to India and a consideration of Indian national character from the point of view of the aspects of personality the author has already described for Americans. The same sort of scrutiny is then accorded to the strongly contrasting Mexican national character. This part of the book is completed with two case histories (that of Ram Dass, an American psychologist turned mystic, and Black Elk, an American Indian shaman) and power visions from the biblical book of Revelation.

From this point, the book turns to the application of the findings to current human problems. The author discusses power motivation and organizational leadership, empire builders, and the psychological basis of war. He draws on earlier work by himself and others to make these final chapters quite persuasive and certainly provocative. He sees the need for power as modified by and interacting with the need for achievement and the need for affiliation. In one interesting chart he presents the temporal relations between the occurrence of wars in which the United States has engaged, balanced or imbalanced motive levels for power and for affiliation, periods of religious revival and social reform, and actual war and peace. This is followed by an extensive discussion of the probable significance of these relationships for the future history of the world.

The last section, titled Are Wars Inevitable? seems to conclude that wars are certainly likely if mankind does not learn to make more consistent use of the tenets of any one of the current world religions. To me this seems akin to the needlessness of most illness: we know enough to keep ourselves healthy, both physically and mentally, yet we do not bestir ourselves sufficiently in applying this knowledge to avoid illness. The causes of both peace and health could be considerably enhanced, I believe, by much more vigorous educational efforts directed at providing the general public with a more adequate basis for making choices.

DOROTHEA C. LEIGHTON, M.D.
Berkeley, Calif.

Childhood Psychopathology and Adult Psychoses, *by Thomas Freeman. New York, N.Y., International Universities Press, 1976, 286 pp., $16.50.*

The value of a theory of adult psychoses in relation to psychopathological development in early childhood is to be measured by the degree to which it gives additional insights into the adult psychoses that can be useful for their understanding, treatment, and prevention. Conversely, data obtained from the study of adult psychoses that provide verification of a particular theory of childhood development are to be considered of great value. This book will be discussed from these points of view.

Dr. Freeman is a consultant psychiatrist at Holywell Hospital, Antrim, Northern Ireland, as well as at the Hampstead Child-Therapy Clinic in London. The title of his book promises to provide useful insights into the continuity or risk factors linking early childhood mental disorders and psychoses occurring in adult life.

From the point of view of psychoanalytic theory, Freeman's exposition is impeccable. He has taken Anna Freud's concept of developmental line and applied it step by step to adult patients he presents in case vignettes. Freeman's basic concepts are elegantly stated:

> There is nothing in these reconstructions to distinguish them from the reconstructed childhood histories of patients who suffer from neuroses and character abnormalities. . . . All that can be claimed on the basis of clinical observation is that those destined to develop a psychosis have failed in varying degrees to extricate themselves partly or wholly, from the earliest narcissistic stage. (p. 181)

That there is a fundamental dichotomy between this method of examination of mental disorder and clinical psychiatry is stated by the author: "The developmental approach to symptomatology avoids the danger of overestimating the significance of the form and content of the clinical phenomena" (p. 33). Indeed, although excerpts are given of patients' verbalizations with a statement of the psychotic diagnostic category to which Dr. Freeman has assigned each one, no organized case history is given that would permit the reader to decide whether these patients were correctly diagnosed. Thus, psychoanalysts are provided a discussion rich in theoretical content, as is attested to by Anna Freud in her introduction, but for those seeking insights that have clinical application in the healing process the discussion has little to offer.

For the child psychiatrist who is not seeking a tour de force of theorization, the precision of analogy also lacks clinical usefulness. One would wish to find some hints in the volume of preventive measures. The key concept is that of "descriptive and metapsychological similarity" (p. xi). This is carried through in each of the adult cases used in the argument, in which clinical excerpts are given together with detailed assignation of these clinically descriptive ideas to points on Anna Freud's developmental line. An example is as follows:

> With the disorganization of psychic structure during the acute psychotic attack, the patient's mental life approximates that of a young child prior to the differentiation of ego and id and self and object. (p. 110)

Throughout the volume analogy is consistently used as if it proved a reality, e.g.,

> During the psychosis Miss M. behaved in a manner akin to that of a child in the pre-oedipal phase insofar as she could not tolerate the frustration of an instinctual need. (p. 145)

Dr. Freeman does not see infantile psychosis as prototypical of the psychoses of adult life; I agree. Further, he does not find any normal or pathological childhood mental state that is an equivalent of the "passivity delusions" (p. 194) of the adult psychotic patient. His conclusion that predisposition to psychotic illness rests on Freud's concept of faulty mental childhood development, as stated in Freud's theories of libido and symptom formation in the neuroses, brings us back to Freeman's starting point: "A theory of predisposition that gives a prominent place to narcissism finds most favor with this writer, in spite of all the difficulties arising from its usage" (p. 278).

For those who believe that Freudian theory of development has been proven, this volume provides a contribution to the argument against those whom the author classifies as revisionists, such as Lidz and his colleagues. However, if *Childhood Psychopathology and Adult Psychoses* is to be examined in terms of its contribution to insights into adult psychoses from actual childhood behaviors or in terms of the degree to which it brings independent confirmatory data to bear on validation of Freudian theory of childhood development, it accomplishes neither purpose.

STELLA CHESS, M.D.
New York, N.Y.

Mental Handicap, *by Brian Kirman and Joan Bicknell. Edinburgh, Scotland, Churchill Livingstone (New York, N.Y., Longman, distributor), 1975, 473 pp., $39.50.*

This book reflects its authors' great clinical experience, gained in an atmosphere both hopeful and realistic, and their sincere regard for the management problems of not only institutions for the care of the mentally retarded but, more important, the families of retarded individuals. The ideal of "normalization" of the environment for the retarded is given its due, but it is not allowed to run to the fadistic extremes that it seems to me to do often in the United States. The authors recognize situations in which a particular handicap changes perceptual capacity to such an extent that normalization of the environment constitutes a disservice to the individual.

One example of this realistic attitude is in the discussion of the value of literacy, in which the authors conclude that this achievement may be given too high a rating as a goal for the mentally handicapped and may lead to a waste of training time. The attitude toward normalization is reflected in the following statement:

> While we may publicly profess our private anxiety to identify with the severely retarded, it would be perilous to ignore the fact that the context in which the severely handicapped learn and develop, not infrequently shows a specific difference when compared to the learning experience of their normal siblings.

Thus the difference between the retarded child and his or her normal siblings lies not only in the retarded child's needs but in our expectations of his or her performance.

Although this book is written from a generous, hopeful, realistic, empathic clinical point of view that is scientific but outstandingly humane, it contains no thorough discussion of the etiology of mild mental handicaps. Half of the book is devoted to the more exotic, distinctly biological syndromes. This section is sound, up-to-date, and well documented, making it a valuable reference section, but, from the point of view of the total problem of retardation, the cases cited make up only a small portion of the caseload of the retarded in any community.

The latter half of the book deals with broader problems of case management and the education of the retarded. This portion of the book is, for the most part, concerned with less retarded individuals. For example, the average IQ of the 40 individuals reported on in an appendix on employment experience is 62.7 (when verbal and performance scores were given they were averaged). The complications listed for these 40 individuals include one case of dystrophia myatonia and one heart lesion; there were no other physical disabilities other than two cases of speech defects and two of small stature. All other complications were in the behavioral sphere; the authors go to some length to stress that such complications must be viewed with great caution as indicators of brain damage.

The point is that the cases dealt with in the treatment and management section of the book are very different from those discussed in such detail in the general section on etiology. For the most part, the individuals referred to in the treatment section appeared to have higher IQs and no or few physical abnormalities, while the cases discussed in the section on etiology were more severe and were usually accompanied by physical abnormalities.

Nevertheless, the latter half of the book is of value. The various types of teaching techniques are well discussed. The issue of sexuality and its management is reassuringly dealt with, and the qualities necessary in the teacher of the retarded are listed and discussed. The assets and problems of behavior modification techniques are briefly taken up. Treatment in the community rather than in an institution is strongly favored, but this view is mellowed by the good clinical sense that pervades the book.

There is a chapter on English laws and regulations dealing with retardation. A similar summary of governmental regulations in the United States would be helpful, but I would not expect English authors to deal with this. The language is English rather than American. This stands out occasionally, particularly in a different use of commas.

In spite of the fact that the treatment and management section of this book addresses itself to milder cases than the section on etiology, *Mental Handicap* has real value.

PAUL V. LEMKAU, M.D.
Baltimore, Md.

Review of Child Development Research, Vol. 5, *edited by E. Mavis Hetherington, John W. Hagen, Reuben Kron, and Aletha Huston Stein. Chicago, Ill., University of Chicago Press, 1975, 590 pp., $17.50.*

This is the fifth in a series commissioned by the Society for Research in Child Development oriented toward a broad interdisciplinary audience of people working with children in research and applied areas (including, of course, child psychiatrists) and presented, according to the editors, with a minimum of jargon and methodological detail.

The editors seem well aware that clinicians and other "tender" professionals are inclined to be psychoallergic to the experimental approach and to react with undue sensitivity to what they perceive, from their special perspective, as irrelevant trivia packaged in elegant statistical methodology. They have therefore attempted to bring together reviews that deal with ecology (of interest to today's child psychiatrist),

cooperation (of interest to the child therapist), the impact of television (of interest to the psychopathologist as well as to all parents), the understanding of social situations and relationships by the child (of interest to the group worker), and problems of attention, learning, and deafness (of interest to the school psychologist). The final chapter is a critical review of research in child abuse that covers most of the literature over the past 15 years. Altogether, it would seem that the clinician's needs have been particularly considered in this volume.

The book gets off to a good start with a contribution on the history of the child development movement by Sears. Because the author was part of the "ancient" history that he sets out to describe, he creates a very living account of the growth of the new discipline. Quotably, he considers "the uneasy mixing of theory and empirical study" and the "tremulous partnership" that continues to exist between academician and practitioner. Sensitively, he addresses himself to the emergence of "empathizable others" and the "empathic ethos" that characterizes this initial era. Competently, he traces the familiar history of the child guidance movement. Sympathetically and yet critically, he considers the monumental contributions of psychoanalysis and field theory.

Sears's essay should be made compulsory reading for every candidate taking Boards in child psychiatry. He stresses the need to return to relevancy as a guide to action, the need to carry out both process and substantive research, the need to treat children as malleable, changing individuals in a changing society, the need to respect the behavior of real people in a real world, the need to consider both innate and acquired factors, the need to deal with both experimental and theoretical issues, and, finally, the importance of thinking of the child as a whole, however nebulous, hollow, and unresearchable such a concept might seem to the investigator.

One cannot help but feel that had all of the chapters been written by Sears the book would have turned out far more readable and memorable. As it is, the other contributors are plagued by the disease of all reviewers, which is manifested by interminable sequences of citations that make the text very heavy going at times. Nevertheless, this in itself does not detract from the general value of volume 5 of this series for clinicians; if they have to work harder for their knowledge this may do them good because their professional diet is frequently overloaded with easily digestible anecdotal ingredients. If they want to keep up with behavioral science, they must accustom themselves to more rigorous fare.

To sum up, this volume provides critical information that should prove valuable to the psychiatric clinician in his or her daily work. It may even encourage some of them to join the Society for Research in Child Development and render it a little more responsive to relevant contemporary problems in the clinical field than it has been so far.

E. JAMES ANTHONY, M.D.
St. Louis, Mo.

Psychological Care of the Medically Ill: A Primer in Liaison Psychiatry, *by James J. Strain, M.D., and Stanley Grossman, M.D. Englewood Cliffs, N.J., Appleton-Century-Crofts (Prentice-Hall), 1975, 214 pp., $12.50.*

As is pointed out in the foreword, this is really a book on Montefiore Hospital. Much of the book is devoted to problems that were encountered in the establishment of meaningful psychiatric liaison there. Although the lessons of these experiences can certainly be generalized and applied in whole or in part to other settings, it is my belief that the attempts to deal with the broad subject of psychological care of the medically ill and with the story of Montefiore Hospital in the same book does not quite allow justice to be done to either subject.

In addition to the introductory chapters and those specifically devoted to the evolution of a liaison program by the primary authors, there is a chapter on "The Current Status of Psychosomatic Medicine" by Edward J. Sachar that discusses the history of theories of psychosomatic illness and touches on the current status of these theories. Dr. Sachar also contributes a chapter on "Evaluating Depression in the Medical Patient."

Norman Altman authors a chapter on hypochondriasis, which he defines as "a chronic condition dominated by preoccupation with bodily function and an unshakable belief that physical illness is present," that is, illness as a way of life and a way of relating. He speaks of the "inability of either psychiatrists or internists to integrate the behavioral and physical aspects of these disorders into a holistic understanding and management of the patient," which may be true. However, I have seen many cases such as those Altman describes handled expertly by the family practitioner of a generation ago. On the other hand, Altman's chapter offers an excellent clinical picture of the condition of hypochondriasis.

Francis D. Boudry and Alfred Wiener present a chapter titled "The Surgical Patient," which seems to be focused primarily on problems with the surgical service and the surgeon rather than problems of the surgical patient. Although this is generally an excellent chapter, one would hope that the authors exaggerate when they state that surgeons are able to recognize "only bizarre manifestations of psychological states . . . and may not have the time, knowledge or motivation to deal with them."

The chapter on the physician's response to the dying patient is covered by James Spikes and Jimmie Holland. Although there is a chapter titled "The Liaison Model of Coronary Heart Disease" that deals with some of the basic psychosomatic concepts of coronary disease and some of the psychological implications of coronary illness, there is no discussion of the very highly developed psychiatric liaison that has been involved with coronary care units in several settings. Other areas in which equally sophisticated liaison has developed in recent years that are not discussed are dialysis and renal transplant and the pain management center.

One might take exception to the chapter titled "The Anatomy of the Teaching Hospital," insisting that the authors have overemphasized the problems created by superspecialization and have overgeneralized them as applying equally to all teaching hospitals. On second thought, however, it would seem to me that the difference is perhaps a matter of degree and that their observations should be taken for what they are worth and applied to the reader's setting when the shoe fits.

The book gives an excellent account of the effort to develop a really meaningful and useful psychiatric consultation service at Montefiore Hospital—to institute in practice what we so often give lip service to, namely, the holistic concept of medicine and genuine concern for the people who happen to contain fascinating organs and pathology. There are many excellent anecdotes related in which the psychological impact of medical illness is illustrated and techniques for its tactful presentation to the nonpsychiatric physician, the medical student, and the nurse are described. There is a brief dis-

cussion of the nurse's role in liaison service, which has been so helpful with the management of the difficult patient not on the psychiatric service.

The brevity of the book is perhaps both an asset and a liability. One might complain that the subject of liaison psychiatry is not really fully covered. On the other hand, for anyone concerned with this subject, there is a great deal of value contained in a relatively brief and very readable document.

HAROLD R. MARTIN, M.D.

Handbook of Evaluation Research, Vol. 1, *edited by Elmer L. Struening and Marcia Guttentag. Beverly Hills, Calif., SAGE Publications, 1975, 676 pp., no price listed.*

Handbook of Evaluation Research, Vol. 2, *edited by Marcia Guttentag and Elmer L. Struening. Beverly Hills, Calif., SAGE Publications, 1975, 716 pp., no price listed.*

Here is everything you wanted to know (well, almost) about evaluation research and a good bit besides. This two-volume set was sponsored by the Society for the Psychological Study of Social Issues, contains 37 chapters by 45 authors, and was meant to be exhaustive. It is exhausting, for certain, but then it can be safely predicted that very few persons will read it through under the same conditions as are necessary for a reviewer. It is called a handbook, and, although it is not quite that, the set will probably be used as a basic reference work. Some of the material has appeared elsewhere in some form or another, but the collection of material is quite useful and of generally high quality and high reader interest.

Volume 1 consists of basic material on evaluation research, beginning with policy and strategy in evaluation research, design of evaluation studies, development of measures, data collection by interviews and records, evaluation through social ecology, data analytic methods, and communication of evaluation results. For the most part the material is well chosen and well presented, the ideas are up-to-date, and in general it is comprehensive and helpful. On the other hand, it must be noted that the presentation is scarcely geared to the novice; it will be most useful to readers who already have a fair amount of experience or training in evaluation research.

Volume 2 is oriented largely to program evaluation in the field of mental health and should be of distinct interest to professionals with responsibility for mental health programs, whether they have a direct responsibility for evaluation or not. There is an initial section on politics and values in evaluation research that is quite stimulating and should be of very general interest, as should the two subsequent chapters on cost-benefit and cost-effectiveness analysis. The latter two chapters will be especially helpful to social scientists with considerable interest and little training in economic analysis. A subsequent section on evaluation of mental health programs includes a mixed lot of chapters reporting specific evaluation efforts or reviewing literature in some area of program performance. These chapters will be of principal interest to professionals in the field of mental health. Volume 2 concludes with three chapters reporting evaluation efforts in the fields of early childhood educational interventions, public health programs, and new careers programs. All three make good reading for those with an interest in the content area.

These two volumes were prepared and edited by thoughtful and experienced workers with a good bit of personal experience in evaluation. They chose materials very wisely from among those available, and they solicited and obtained pieces from some (one is tempted to say most) of the best-known figures in evaluation research so that the work is both stimulating and authoritative. The cost of the two volumes together is high; not many individual readers may feel that the investment is worthwhile. However, I predict that persons with a continuing commitment to program evaluation at a professional level will, if they acquire these volumes, refer to them frequently and with profit.

Research in Psychophysiology, *edited by Peter H. Venables and Margaret J. Christie. New York, N.Y., John Wiley & Sons, 1975, 437 pp., $32.00.*

The editors have collected and edited a series of excellent essays on psychophysiological problems for researchers and clinicians. Peter Venables writes two excellent reviews himself; these give the book more than an additional fillip.

The book is divided into three sections covering a wide array of methodological problems and states as well as subjects that are clearly defined as psychophysiological. I am unaware of the definition and boundaries of "traditional" psychology, experimental psychology, and physiological psychology. However, for psychiatrists today psychophysiology must be considered in the mainstream.

That the "classical" boundaries between discipline areas have long since been breached is clearly exemplified in Venables' review of schizophrenia and his epilogue chapter, which includes comments on what he terms "high risk" research. I feel that these two chapters would be well worth the price of the book.

I found the chapters on memory, pleasure (including humor), psychopathy, and precursors of disease especially well written. From the psychological laboratories in Stockholm Marianne Frankenhauser's review of sympathetic-adrenomedullary activity, behavior, and the psychosocial environment raises tantalizing questions about aspects of cognition and catecholamine secretion or arousal.

The chapter on psychopathy by Robert Hare of British Columbia, which includes subsections on autonomic correlates and cortical correlates, raises sophisticated issues about the mechanism of learning at different integrative levels. Irene Martin of the London Insititue of Psychiatry writes a fine chapter on conditioning with a review of its history and a breakdown of the two simple conditioning models. The days of the simple S-R response are over. The problem of understanding the complex interactions of cognitive and autonomic factors as well as behavioral and perceptual responses may initially make one feel that the walled-in universe of understanding has fallen in.

Indeed, the book forces all clinicians to reevaluate and assess again their clinical experience by looking more closely at the biological and physiological bases of behavior. Earlier rigid theoretical views are in a shambles and must be reexamined in the light of existing physiological data. The psychophysiologists are challenging the classicists of all stripes, especially analytic theoreticians, to see how complex the world is.

I feel that this book is especially valuable for residents in

training and clinical researchers. The bibliographies are adequate for all serious students. Practitioners who are removed from the laboratories may find the reading difficult but worth the investment of time.

The Insanity Defense: A Blueprint for Legislative Reform, *by Grant H. Morris. Lexington, Mass., Lexington Books (D.C. Heath and Co.). 1975, 126 pp., $10.00.*

This book reflects the author's views on the problem of the insanity defense that were submitted to the Criminal Code Commission of the Arizona State Legislature. Professor Morris brought to this task his own rich experience as staff attorney of the Institute of Public Administration in New York; he also holds faculty appointments in both medicine and law.

This work is an excellent introduction to the complexities, paradoxes, good intentions, and failings of the legal system in its attempt to deal with the moral issue of guilt and the historically derived but far from clear acceptance of psychiatric testimony in such determinations.

Professor Morris has produced a monograph that will be particularly useful to the psychiatrist preparing for his specialty Boards. Those who are interested in issues of forensic psychiatry and want a clear and ready reference to the different standards pertaining to the insanity defense in different jurisdictions will also find this book useful. Written with an acceptance of psychiatric expertise in general (a refreshing change), it recognizes that psychiatric expertise and diagnosis are not readily translated into social and legal terms. A particular strength of the book is the discussion of the complexities and nuances of language in the various standards governing the insanity defense as they have been introduced either by courts, as in the case of the Durham rule, or by legislative statute, as in the adoption of the American Law Institute's Model Penal Code.

Professor Morris makes one comment that deserves particular emphasis and general recognition. He implies that problems in the area of mental health are aggravated by adversary debate in court. Coming from an attorney, this is doubly refreshing because we live in a setting in which complex public policy issues are too often argued, and argued with a bias, in court. Morris counterposes the synthetic and conciliatory process of legislation and advocates this as the best way of achieving real progress. On the basis of his experience, he finds this the most constructive approach for the resolution of the serious problems that continually confront us in the mental health area.

Professor Morris makes one suggestion that, in many ways, appears to be an improvement over the standard set by the American Law Institute (ALI) but that possibly opens up a Pandora's box for our society. He advocates the following standard as an improvement over that of the ALI:

> A person is not criminally responsible for his conduct if, as a result of impairment of his mental or emotional processes or behavior controls, he lacked, at the time of such conduct, substantial capacity either to appreciate the wrongfulness of his conduct or to conform his conduct to the requirements of law.

The wording and the intent of this is to deemphasize medical testimony and permit introduction of evidence that describes the defendant's social and emotional impairment as well as his or her psychological impairment. Whether our society and public policy is well served by such an enlargement of the insanity defense is, I think at this point, not proven and probably not generally accepted.

The concept of the bifurcated trial appeals to many psychiatrists. In the first stage, the court determines whether the defendant committed the act of which he is accused. In the second part, the court with psychiatric advice makes a determination of the mental state of the accused at the time of the act and decides the sentence, punishment, or rehabilitation. Professor Morris cogently argues that in our legal system such a proposition is contrary to the fundamentals of law and runs counter to established precedent. To employ such a bifurcated trial would, indeed, take away the right of the accused to present in front of his peers a defense that, regardless of the physical act, evil intent was absent. Without evil intent there can be no guilt and no verdict of guilty.

Finally, Professor Morris takes to task most of the jurisdictions for holding individuals exculpated by reason of insanity to very stringent criminal standards of confinement. He finds that this is not only illogical but also inequitable. He also argues strongly the merits of defense based on the diminished responsibility test and would like to see the following used:

> Evidence of impairment of the defendant's mental or emotional processes or behavior controls shall be admissible whenever it is relevant to prove that the defendant did not have a state of mind which is an element of the crime charged. Whenever the court or jury finds a defendant not guilty because of such proof, the trial court may order the prosecutor to commence civil commitment proceedings in accordance with the procedures of the mental health code.

As a profession, psychiatry has failed to develop ethically sound policies as to the conditions under which we will act and the lengths to which we will go in the adversarial process. Only sophisticated expertise plus strong professional integrity will protect the practicing psychiatrist from being enveigled and traduced into uncomfortable and untenable legal situations. Seymour Pollack has advocated accreditation for forensic psychiatrists for some time (1). If the specialty of psychiatry cannot make this step, perhaps it is time that legislatures and courts pay significant attention to the training and expertise of psychiatrists and limit the testimony of experts to those who are indeed experts.

Report of the Secretary
Summary of Meetings of Board of Trustees and Executive Committee
May 1975–May 1976

IT IS A personal privilege as well as my constitutional duty to report the actions of the Board of Trustees since the last annual meeting. With the invaluable collaboration of Dr. Sabshin, Mrs. Ruth Arnold, and others in the Central Office, I have subdivided the actions into several categories. Each category has been noted as briefly as possible; no transactions have been omitted other than confidential judgments on ethics. As a preliminary summary, I shall highlight the detailed report.

Suggested revisions of the Constitution and By-Laws. Since the Board withdrew its initial revisions of our Constitution for further improvement through consultations with district branches, area councils, and the Assembly, I will summarize this section very briefly.

In accordance with the mandate of the Key Conference that the policy-setting bodies and the administration of APA be made more alertly sensitive and reactive to the interests and wishes of the membership, a task force composed of representatives of the Assembly and the Board met repeatedly with the Committee on Constitution and By-Laws, and later with expert legal consultants, to revise our Constitution in optimum fashion. Insofar as the time schedule prescribed by the Key Conference permitted, input was solicited from the district branches and area councils. By consensus, the following amendments were proposed by the Board for Assembly approval: 1) a constitutional preamble that more clearly states the social and humanitarian as well as the scientific ideals and objectives of APA; 2) a reconstituted Assembly with representatives more democratically nominated and elected and with special minority representation, thereby being more responsive to regional and interregional interests; 3) an Assembly Executive Committee (with only two representatives from the Board) to which many of the fiscal and organizational initiatives of the present Trustees would be transferred; 4) a Board of Trustees reduced to the national officers, the Speaker and Speaker-Elect of the Assembly, and four Trustees-at-Large to encompass the national and international interests of the Association (the alternative of seven Area Trustees was seriously considered); 5) a dynamic interrelationship between the Assembly and the Board was envisaged so that each, with the approval of the other, could effect action for the benefit of APA—pocket vetoes would be eliminated, and occasional differences resolved either in a joint conference committee or by the vote of the membership; 6) a new Committee of the Association composed of two past Speakers, two past Presidents, and two general members to serve as additional ombudsmen for the membership; 7) improved provisions for direct action by the membership through initiative resolutions and mailed ballots for setting of policy, for recall of any national officer, and for future amendments. Since our articles of incorporation specified a single administrative body, and some of these revisions may also have significant bearing on our IRS status, lawyers were consulted and conflicting opinions considered.

The Assembly. The Trustees approved and funded a nation-wide plan to implement district branch peer review programs.

Councils, committees, task forces, and commissions. The Trustees 1) established a new Council on Children, Youth, and Their Families, with initial funding; 2) established a new Joint Commission on Public Affairs with a salaried director to promote and maintain the optimum public image of psychiatry as a medical as well as a psychosociological specialty; 3) approved continued medical training as essential in all psychiatric residency programs; 4) reinstituted the Commission on Drug Abuse; and 5) approved a survey of electroconvulsive therapy by a task force to be funded by special grants.

Elections. The Trustees drafted an ethical code for all candidates, arranged for rotation of their listing on ballots, deleted current officers' names from all voting stationery, prohibited official recommendations or the use of organizational funds, and took other steps to assure that APA elections at all levels be conducted in as fair and dignified a manner as possible.

Insurance. The Trustees approved tax deferral plans and explored the availability of favorable professional liability rates for APA members and authorized an audit of the Retirement Plan Trust and its transfer to a financially responsible corporate trustee.

Legal matters. The Trustees 1) considered that having APA act as its own malpractice insurer was inadvisable; 2) declined to take a legal position as to third-party payments to the American Association of Marriage and Family Counselors,

This is an edited version of the report presented by the Secretary to the annual business meeting in Miami, Fla., May 11, 1976.

Inc., versus CHAMPUS; 3) promoted more effective liaison between district branches and the APA Commission on Judicial Action; 4) initiated inquiry as to a separate emergency litigation fund that would not impair our favorable IRS status; 5) authorized an initial salary for a staff expert on legislation to monitor the psychiatric implications of the National Health Planning and Resources Development Act of 1974 (P.L. 93-641) and to advise as to favorable mental health provisions; and 6) approved having representatives from each state on the renamed Joint Commission on Government Relations.

Liaison with other organizations. The Trustees implemented closer cooperation with the American Board of Psychiatry and Neurology as to policies, optimal APA representation, conjoint training in medicine, neurology, psychopharmacology, crisis and community care, methods of examination, and issues related to certification and recertification and voted to admit the Coalition for Alcoholism Program Accreditation to the JCAH Accreditation Council.

Meetings. The Trustees approved cosponsorship of the Conference on Psychiatric Classification in June 1976, a joint meeting with the Canadian Psychiatric Association in 1977, the World Federation for Mental Health in Vancouver in 1977, the Second Pacific Congress of Psychiatry, probably in Honolulu in 1980, and other conjoint or sponsored meetings with appropriate conditions and at no expense to APA. (Atlanta, Ga., was selected for the 1978 annual meeting.)

Membership matters. The Trustees interpreted the By-Laws to read that members who forfeited membership-at-large must continue membership in a district branch and endorsed Assembly policy that transfers of membership must be approved by both the district branches involved and ethical qualification be reviewed during such transfers.

Position statements and resolutions. The Trustees 1) drafted an urgent communication to Health Systems Agencies that Public Law 93-641 should hold mental and physical health to be inseparable; 2) approved racial and ethnic desegregation in all hospitals, not only in public ones; 3) clarified the relative qualifications and responsibilities of medical versus nonmedical administrators; 4) joined with many other national and international scientific organizations in protesting the resolution of the United Nations General Assembly equating Zionism with racism as dramatically contradicting its previously instituted "Decade Against Racial Discrimination"[1]; 5) approved, with modification, new "Guidelines for Continuing Education."

I trust that every member of APA is aware that he or she can attend any session of the Board or of any APA component other than those devoted to judging ethical complaints. If attendance is impractical, I shall welcome correspondence on any topic for either direct action by the Trustees or forwarding to the relevant council, commission, committee, task force, or APA staff for appropriate consideration and action.

My prime function as Secretary has been and will be to keep no secrets from the membership, other than confidential ethical proceedings, and to invite your guidance in Association matters as indicated. My detailed report begins with the Constitution and By-Laws because of its immediate relevance to membership action. The remaining categories are listed in alphabetical order. The Board (or its Executive Committee acting as its agent) took the following actions.

[1]On April 28, 1976, Ambassador William Scranton asserted that the policy of the United States was identical with that expressed by APA.

CONSTITUTION AND BY-LAWS

1. Accepted the Assembly's recommendation to add the advocacy function for providing mental health services for patients and the public as a specific objective of the Association (Bd., May '75); approved the recommendation of the Committee on Constitution and By-Laws for its inclusion as (f) of Article II, Section 1 (Bd., Dec. '75); and at a special meeting adopted the language, "to promote the best interests of patients and those actually or potentially making use of mental health services," as being more in line with the APA articles of incorporation (Bd., Mar. '76).

2. Approved the Constitution and By-Laws Committee's (CCBL) recommendation that Article III be amended to include a new category of Provisional Members, who shall be "physicians . . . in their first year of an approved psychiatric residency training program, or approved internship preparatory to entering such an approved psychiatric residency," and specified that the category shall be without voting privileges (Bd., Dec. '75).

3. Approved new wording in Chapter Two, Section 1, of the By-Laws for membership processing by providing that an applicant for membership "may be refused election or promotion to more advanced membership, or transfer to another district branch, on the basis of the provisions of Chapter One of the By-Laws or on the basis of criteria of ethical and professional suitability established by the Board and the Membership Committee and applied by the appropriate district branch" (Bd., Dec. '75).

4. Approved amending Chapter Three, Section 3, of the By-Laws to reduce ambiguity regarding eligibility of Board members in unexpired terms and reelections by specifying: "An appointed Trustee who fills an unexpired term is eligible for election to a full term. An elected Trustee, following a three-year term, may succeed himself. Following two full terms, a Trustee becomes eligible for election again only after an interval of three years" (Bd., Dec. '75).

5. Approved the CCBL recommendation for amending Chapter Seven, Section 6, of the By-Laws to give the Assembly the same opportunities and remedies as the Forum without undue interference by the Board; and provided that a "circulated referendum shall carry with it both the opinion of the Board and the opinion of those initiating the referendum" (Bd., Dec. '75).

6. Approved the CCBL-recommended amendment for Chapter Eight, Section 6, of the By-Laws—considered advisable based on information received from the Postal Service regarding second-class mail and the IRS—to specify that the dues "will include amounts allocated to subscriptions for *The American Journal of Psychiatry* and for *Psychiatric News*. The membership application shall contain a provision for allocation of a specific portion of the dues to pay the cost of periodical subscriptions to these publications" (Bd., Dec. '75).

7. Adopted the CCBL recommendation and authorized amendments to permit substituting the term "chairperson" for "chairman" at every point in the Constitution and By-Laws where it appears (Bd., Dec. '75).

8. Approved in principle the recommendations of the Joint Conference Committee on the Key Conference Recommendations as guidelines for constitutional change (Bd., Feb. '76).

9. Took the following actions to provide an enabling mechanism "which leaves the options open for action on the report within the March 11, 1976 deadline, without mandating such action": approved appointment of an Ad Hoc Com-

mittee on the Revision of the APA Constitution, comprised of the Speaker and Speaker-Elect, the President and President-Elect, the Treasurer, the Committee on Constitution and By-Laws, and certain other members of the Joint Conference Committee on Key Conference Recommendations; charged this ad hoc committee (under the chairmanship of Dr. Marmor) with submitting specific or alternative amendments to the Constitution along the lines of the Joint Conference report and in the light of past and future discussions by the Assembly and the Board, for approval by the Board and passage or rejection by the membership; and charged this ad hoc committee with distributing the report of the Joint Conference Committee, the analysis of this report by the Committee on Constitution and By-Laws, and other relevant documents to the area councils and district branches, with a request for feedback (Bd., Feb. '76).

10. Approved the entire proposed Constitution and By-Laws as a complete document, with the minor wording and grammatical changes that had been suggested in the discussion (Bd., Mar. '76).

11. Asked that the completed, approved Constitution and By-Laws be transmitted to the Secretary prior to March 11, 1976 (60 days before the annual meeting), that staff investigate the suggested option contingencies, but that this investigation not preclude its presentation before the deadline (Bd., Mar. '76).

12. Authorized up to $2000 for the purpose of obtaining a second opinion regarding the legal aspects of the proposed restructuring of the American Psychiatric Association (Bd., Mar. '76).

13. In accordance with their December ruling that deficit spending must be approved by a two-thirds vote of the Board, the Trustees approved the expenses of the three days of meetings involved in this proposed revision of the APA Constitution and By-Laws: the Board of Trustees meeting on March 7, 1976, and the two-day "constitutional mini convention" that preceded it on March 5 and 6 (Bd., Mar. '76).

ASSEMBLY

1. Approved increasing the Assembly budget for 1975–1976 by $3500 to provide for implementation of a pilot insurance coding project (first proposed by the Task Force on Confidentiality in Relation to Third-Party Payment) to devise a coding system by which the use of clinical diagnoses could be avoided (Ex. C., Apr. '75).

2. Approved the Reference Committee's recommendation for a plan to implement peer review—in which one member of the Peer Review Committee will visit the district branches (40 this year and 40 the next year) to help develop an effective peer review mechanism in every district branch; specified that the program would have to be implemented in such a way that $22,400 not be overreached; and left it to the discretion of the Medical Director to phase in the program within these policy specifications (Bd., Dec. '75).

COUNCILS, COMMITTEES, TASK FORCES, AND COMMISSIONS

1. Terminated the Ad Hoc Committee To Plan the Key Conference, with thanks to the committee and APA staff; asked the President to appoint an Ad Hoc Committee on the Key Conference Recommendations, in the manner of the Assembly task force already designated, to move in the direction of implementing the Key Conference suggestions (Bd., May '75).

2. Renewed three ad hoc committees for another year: Ad Hoc Committee To Plan a Conference on Law and Psychiatry, Ad Hoc Committee on Election Procedures, and Ad Hoc Committee on Interprofessional Services (Bd., May '75).

3. At the request of the Editor, approved second terms on the Editorial Board of the *American Journal of Psychiatry* for Drs. Morris A. Lipton, John C. Nemiah, and Chester M. Pierce (Bd., Dec. '75).

4. Asked the Reference Committee to explore fully the fiscal aspects of establishing another council (Bd., May '75); approved establishment of a Council on Children, Youth, and Their Families, beginning April 1976, with the stipulation that the charge be refined and structure be kept minimal at first (Ex. C., June '75); approved the charge developed by the Commission on Childhood and Adolescence; and accepted the title change to "Council on Children, Adolescents, and Their Families" (Bd., Dec. '75).

5. Authorized $1500 additional funding to support travel expenses for members of the Committee of Residents to meetings other than the annual meeting; and endorsed the Reference Committee's commendation of the Committee of Residents for its extensive activities during the past year on public information, liaison activities, recruitment, problem solving, and ongoing program review (Bd., Dec. '75).

6. Approved establishment of a Committee on Advertising Policy within the Council on Internal Organization, and authorized $300 in additional funds in fiscal year 1976–1977 to support both this committee and a Task Force To Study the Impact of Potential Loss of Pharmaceutical Support if the policy were changed—with the request that the Council chairperson seek and solicit participation by the Assembly (Bd., Dec. '75).

7. Endorsed the move of the Committee on Conventions to merge the subcommittees on technical and scientific exhibits, and approved the Council's appointment of an Ad Hoc Committee on Spouses' Scientific Program, and authorized funding up to $1000 (Bd., Dec. '75).

8. Approved the Reference Committee's recommendations that it become APA policy that all new awards established by the Association be self-sustaining, the Medical Director be authorized to seek additional funds to continue the Hofheimer Award, and the Deputy Director for Business Administration be authorized to develop an APA Award Fund, using the unrestricted funds in the grants and awards account and funds presently in the special purposes account to establish new awards where appropriate and to help fund existing award programs that run out of funds (Bd., Dec. '75).

9. Endorsed the principle of developing a membership brochure as suggested at the Key Conference, and asked staff to explore the revision with appropriate committees, including the Committee on Membership, the Assembly Membership Committee, and the Committee of Residents (Bd., Dec. '75).

10. Authorized the Medical Director to seek outside funding to support two studies by the Membership Services and Studies Division: one to identify nonmember psychiatrists, and the other to conduct a manpower survey of nonmember and member psychiatrists (Bd., Dec. '75).

11. Asked the Committee on Public Information to consid-

er development of a public affairs network similar to the district branch legislative network (Ex. C., Sept. '75); approved establishment of a Joint Commission on Public Affairs, to report directly to the Board of Trustees and the Assembly, appointments to be made jointly by the President and the Speaker: authorized funds (up to $30,000) to hire an Assistant to the Director of Public Affairs, and left it to the discretion of the Medical Director to implement by degrees, within available funds for program expansion (Bd., Dec. '75).

12. Gave approval to the sense of an Assembly resolution regarding establishing requirements for exposure to clinical medical responsibility as part of the graduate psychiatric training leading toward certification by the ABPN; and agreed to use the resources of the APA to facilitate graduate psychiatric education to include responsibility for the care of the medically ill patient (Ex. C., June '75).

13. Strongly endorsed the Reference Committee's commendation of Howard M. Kern, M.D., for his service to APA as Associate Director for Continuing Education and his years of assistance to the Council on Medical Education and Career Development (Bd., Dec. '75).

14. Approved the recommendation by the Committee on Women and the Council on National Affairs that child care be arranged during each APA annual meeting, with the understanding that such services shall be self-supporting—and discontinued if they are not (Bd., Dec. '75).

15. Approved establishment of a Committee on Indian Affairs as the task force so designated is being terminated; and noted that a number of consultants are being appointed, at no additional expense to the APA—their funding to come from the agencies they serve, or from grants supporting the work of the committee (Bd., Dec. '75).

16. Authorized the Committee on Indian Affairs to use $1500 of unspent funds received from the Ittleson Family Foundation grant to publish a monograph on mental health problems of Indian youth—continuation of a project made possible by a contract with the Indian Health Service (Bd., Dec. '75).

17. Approved establishment of a Committee on the Mental Health of Spanish-Speaking People in the United States within the Council on National Affairs (in May 1976); and endorsed the suggestion to the President that, where appropriate, effort be made to appoint qualified Spanish-speaking psychiatrists to the APA component (Bd., Dec.'75).

18. Endorsed the recommendation that all minority group psychiatrists be included when consideration is given to selections for observer/consultant positions (Bd., Dec. '75).

19. Approved the Reference Committee's recommendation for establishment of a Committee on Confidentiality in the Council of National Affairs, consisting of seven members (one from each area) chosen on the basis of their experience and demonstrated knowledge in this field; and authorized $2500 for its support (Bd., Dec. '75).

20. Reconstituted the Commission on Drug Abuse to permit continuation of its work until May 1976 (its normal termination date), during which time recommendations will be developed by the Council on Research and Development for entities dealing with enduring functions of the Commission (Bd., Apr. '75).

21. Strongly supported the Reference Committee recommendation that the Council on Research and Development, in collaboration with the Medical Director, be authorized to seek outside funds (about $30,000) to support survey activities of the Task Force on Electroconvulsive Therapy, in view of the present crisis over ECT (Bd., Dec. '75).

ELECTIONS AND TERMS

1. Authorized future APA elections to be conducted within the guidelines of systematic rotation of names of candidates within each office on a single (vertical, for ease of coding), ballot type, as recommended by the Ad Hoc Committee on Election Procedures, inasmuch as the influence of vertical or horizontal ballots revealed no consistent pattern of outcome, but influence of name order on the ballot cannot be entirely ruled out, and inasmuch as systematic rotation of names does not involve more than a few hundred dollars in printing and mailing costs, exclusive of staff time (Ex.C., June '75).

2. Approved having the newly adopted policy of systematic rotation of names on the ballots incorporated into the APA *Operations Manual* (Ex.C., Sept. '75).

3. Approved the recommendation of the Ad Hoc Committee on Election Procedures for continued use of the unidentifiable ballot, until there is a report expressing the sentiment of the Assembly on the issue (Ex.C., Sept. '75).

4. Approved two recommendations of the Ad Hoc Committee on Election Procedures: that APA continue the procedure of not supplying postage paid return envelopes for ballots; and that the return envelope be preprinted with the APA address in the upper left corner (Ex.C., Sept. '75).

5. In a mail ballot of the Board of Trustees, regarding the eligibility of Dr. Jack A. Wolford to succeed himself as Vice-President (Chapter Four, Section 7, of the Constitution and By-Laws), the majority favored the interpretation that as he had been elected to a partial term in a year when policy regarding length of term was changed, he was eligible for election to a full two-year term as Vice-President of APA (Ex.C., Sept. '75).

6. In order to minimize prejudicing the votes, adopted the recommendation of the Ad Hoc Committee on Election Procedures that the names of officers appearing on official stationery be blocked out on the covering letter for the ballot, which will be signed by the President of APA, because he cannot succeed himself and is not likely to run for any other office (Ex.C, Sept. '75).

7. Approved the recommendation of the Ad Hoc Committee on Election Procedures for regular publication in *Psychiatric News* of information stating that district branch membership is required for membership in the American Psychiatric Association and that at-large members are not eligible to vote in local or area trustee elections (Ex.C., Sept. '75).

8. Authorized analysis and publication in the *American Journal of Psychiatry* of data from the 1974 election ballots (voting patterns of groups, defined by sex, member class, age, length of membership, and Board certification status)—after assurance that individual identification of voters is not possible and not at issue (Ex. C., Sept. '75; ratified, Bd., Dec. '75).

9. Adopted unanimously the majority recommendation of the Ad Hoc Committee on Election Procedures that any officer of the Association shall not use his/her official title or APA stationery to endorse any candidate, amendment, or referendum in connection with an APA election (Ex.C., Sept. '75).

10. Approved the recommendation of the Ad Hoc Committee on Election Procedures that a general statement on campaign financing be adopted by the Executive Committee, and approved the following guidelines: that no APA area or district branch funds or services be used for election campaigns; that only APA members or groups of members be al-

lowed to contribute financing or other resources to electioneering for nomination and election—no organization, institution, individual, or group of individuals outside the APA may contribute to any candidate; that at least one week before the election, each candidate will be expected to submit an overall statement affirming that to the best of his knowledge his campaign was conducted within the guidelines set forth in these actions; that these guidelines will become mandatory for nominations and elections referable to the year 1977. Requested their immediate publication in *Psychiatric News*, strongly urging concurrence by all candidates in the election for the current year (Ex.C., Sept. '75).

11. Verified two petitions concerning the American Board of Psychiatry and Neurology, Inc., for the 1976 balloting, and ratified the Executive Committee's acceptance of the Board's statement on the ballot (Bd., Feb. '76).

12. In answer to three complaints alleging that persons had violated the guidelines for campaigning in the 1976 APA elections, authorized the Medical Director to write to remind them that use of district branch stationery or envelopes is a violation of procedures described in the APA *Operations Manual*; and specified further that the current guidelines should be sent to all candidates routinely and publicized in *Psychiatric News* (Bd., Feb. '76).

FISCAL MATTERS

1. Approved raising the APA contribution to the National Coalition for Health Funding from $1000 to $2000, for one year, in response to the new funding formula by this coalition, but asked for investigation before another year, to be sure the Association is getting its money's worth (Ex.C., Apr. '75).

2. Approved increased funding from $.50 to $1.00 per voting member for the Council of Medical Specialty Societies, which raises the annual amount from $11,000 to $20,000—but asked for further discussion regarding the function, total budget of the CMSS, and APA input (Ex.C., Apr. '75).

3. Approved the Museum and Library budget presented at the December 1974 meeting of the Board, with one change: reallocating the $20,000 for a bicentennial exhibit to bring the inventory of archives up to date and to develop a permanent archive and rare book display in the Museum area (Bd., May '75).

4. Asked the Budget Committee to study the mechanism for funding the Museum, and in the meantime approved retaining the present loan mechanism for fiscal year 1975–1976; authorized a loan of $196,934 from APA to the American Psychiatric Museum Association (Bd., May '75).

5. Approved a plan of financing the operation of the APMA through grant awards (instead of loans as before) retroactive to April 1, 1975 (Ex.C., Sept. '75).

6. Approved changing the APA fiscal year to the calendar year, effective on January 1, 1977—subject to approval by the Internal Revenue Service—and approved the budgetary arrangements suggested to achieve the changeover when approved.

7. Approved payment of an additional $500 to the National Association for Mental Health, toward settlement of the outstanding balance of the attorney's fee for Mr. Wagshal in the impoundment suit that resulted in the release of $126 million for mental health research and training and for alcoholism programs (Ex.C., Sept. '75).

8. Approved a proposed increase in subscription rates for the *Hospital & Community Psychiatry* journal effective January 1, 1977: foreign, from $15 to $18; domestic, from $12 to $15; and approved the special reciprocity rate to members of the American Psychological Association (Ex.C., Sept. '75).

9. Approved borrowing $100,000 for an advance to launch the VI World Congress of Psychiatry, the money to be used to cover past and future expenses in the planning and development of the Congress, with the proviso that the WPA agree in advance of the loan to reimburse APA for all expenditures, plus interest (Ex.C., Sept. '75).

10. Approved a Joint Meeting with the Caribbean Psychiatric Association and the Puerto Rican Medical Association Section on Psychiatry and Neurology in San Juan, Puerto Rico, following the May 10–14 Miami meeting, and authorized advancement of seed money in the amount of $2500 (Ex.C., Sept. '75).

11. Approved the staff recommendation for an 11% rise in fees for the Psychiatric Knowledge and Skills Self-Assessment Program III: residents, $20; members, $35; nonmembers, $50. Approved contracting with the Educational Testing Service to provide complete marketing and distribution services of PKSAP-III at an estimated cost of $16,355 (money to be loaned and recouped from sales); and authorized carry-over of budget funds from fiscal year 1975–1976 to 1976–1977, as the bulk of the expenses will come due during the latter part of 1976 (Bd., Dec. '75).

12. Approved a 50% rise in APA dues in most categories of membership (with an extra rate of increase for Associate Members, as recommended by the Budget Committee), with the specific understanding that the expected overage created in the 1976–1977 fiscal year will go into reserves as an act of prudence, and not be available for expanded programs (Bd., Dec. '75).

13. Endorsed the Budget Committee's recommendation for a 5% cost-of-living increase to APA employees, retroactive to October 1, 1975, in keeping with the recent federal government increase (Bd., Dec. '75).

14. Approved adoption of the following schedule of registration fees for the annual meeting: students, $15; nonmembers, $60; nonmember spouses, $10; foreign visitors, $20; one day, $15 (Bd., Dec. '75).

15. Approved the entire budget for fiscal year 1976–1977 (Bd., Dec. '75).

16. Approved a policy that spending shall not exceed estimated available revenues without the approval of a two-thirds vote of the governing body—as a reminder that programs are being approved for which funding is not available except through reserves (Bd., Dec. '75).

INSURANCE

1. Approved the tax-deferred annuity program formal plan "as an accommodation to and for the benefit of those of its members who are eligible to participate . . . in accordance with the provisions of Section 403(b) of the Internal Revenue Code of 1954, as amended" (Bd., Apr. '75).

2. Approved the recommendations of the Committee on Member Insurance and the Reference Committee that: rates for professional liability insurance for APA members be changed in accordance with the submitted schedule; that filings for the states of California, Florida, New York, and Ohio be delayed until after January 1, 1976; and that a study be made of actuarial problems where serious rate difficulties exist between different companies in the same state (Bd., Dec. '75).

3. Approved dissolution of the Retirement Plan Trust, and

authorized the trustees of the APA retirement plans to transfer the appropriate functions of that trust to a corporate trustee (e.g., a bank) or other appropriate investment custodian—with the understanding that the Retirement Plan Trustees will present a detailed proposal for final approval at a later date; and noted that these actions will in no way jeopardize existing member pension benefits (Bd., Dec. '75).

4. Approved one-year funding for a Task Force To Study Problems in Obtaining Insurance for People with Previous Psychiatric History (to be established as a subordinate unit of the Committee on Member Insurance) to consider such problems and possible solutions, as a trial-run review committee function for APA members (Bd., Dec. '75).

5. Ratified an emergency action taken by the President to approve and execute a contract between the APA Retirement Plan Trust, executed for the Association by the Trustees of the Trust and APA, and Deferred Compensation Plans, Inc., and its wholly owned subsidiary, DCP Administrations, D.C. Corporations, to act as administrators of the Trust under the terms and conditions provided for in the contract (Bd., Feb. '76).

LEGAL MATTERS

1. Accepted the recommendation of the Chairman of the Commission on Judicial Action that it is not feasible for APA to form its own malpractice insurance company, but to move toward getting a better agreement with APA's insurance carrier (Bd., May '75).

2. Authorized the Chairman of the Commission on Judicial Action to pursue negotiations—if the law firm and the Washington Psychiatric Society can get together on a pro bono brief in the St. Elizabeths case, APA will add its name to the brief as amicus curiae (Bd., Apr. '75).

3. Concurred with the recommendation of the Commission on Judicial Action that the National Organization of Women in Kentucky may cite APA's strong public position on the rights of homosexuals but that the Association does not have the resources to pursue such litigation all over the country (Ex.C., June '75).

4. Gave no official endorsement either to CHAMPUS or the American Association of Marriage and Family Counselors, Inc., in their litigation arising from termination of CHAMPUS payments to marriage and family counselors, but favored issuing a general statement that while APA does not wish to set limitations on who provides treatment, the Association is aware that it is not possible realistically to fund all services that are potentially health related, including services that may be considered under the rubric of primary prevention (Ex.C., June '75).

LEGISLATIVE MATTERS

1. Empowered the Medical Director to engage a highly skilled person to assist in writing regulations and following up on all aspects of the National Health Planning and Resources Development Act of 1974 (P.L. 93-641) in the most effective way possible to the interests of psychiatry; authorized $15,000 now to hire a full-time person to monitor and have input into the regulations and report back to the Board and the field on the implications of what is being developed (Ex.C., June '75).

2. Approved a change in title to redesignate the Joint Commission on Legislation as the Joint Commission on Government Relations, to align its title with the staff division related to it; and noted that this did not indicate any change in function or power; approved the Commission's suggestion (for a trial period of three years) that each state have at least one legislative representative—with particular reference to the Intermountain, North Pacific, and Nebraska-South Dakota District Branches—an additional five legislative representatives; asked that appointments be made in time for attendance at the next Institute on Government Operations in March 1976; and authorized $5000 to cover the additional expense involved (Ex.C., Sept. '75).

3. Approved the Reference Committee's recommendation that the Joint Commission on Government Relations pursue communication about matters pertinent to the Executive and Legislative branches of the federal government (Bd., Dec. '75).

4. Endorsed the suggestion of the Commission on Judicial Action that the district branches appoint appropriate members to district branch commissions whose function would be to consider local branch participation in litigation affecting the practice of psychiatry in that district; to serve as intermediaries with the national Commission; and to set up liaison with the local branch of the bar association (Bd., Dec. '75).

5. Endorsed the decision of the Commission on Judicial Action to urge the Northern Texas Chapter of the Texas District Branch not to use the Wyatt Standard, as not being good enough; and the further suggestion of the Commission that in terms of individual patients and their individual rights, the court should consider a review scheme or appeal scheme such as an ombudsman, and that the court be informed by the Texas District Branch of the dangers of precipitous deinstitutionalization (Bd., Dec. '75).

6. Asked the Speaker and the President-Elect to consult with the Assembly and the Reference Committee as to a separately funded emergency psychiatric litigation fund and as to how such a fund might be developed outside the APA budgetary structure (Bd., Dec. '75).

LIAISON WITH OTHER ORGANIZATIONS

1. Approved inviting APA representatives to the American Board of Psychiatry & Neurology, Inc., to suggest a method for periodic (i.e., annual or semiannual) consultation with the Board of Trustees on important matters of policy; asked that subsequent candidates for appointment be informed of this consultation obligation; and asked that the gist ot the discussion be sent to the ABPN with the suggestion that they consider methods for inviting other psychiatrist members of the ABPN to participate (Bd., Apr. '75).

2. Adopted a plan for securing nominations for Directors of the ABPN in which staff will write letters to each of the candidates to ask if the candidate will serve if nominated and elected, if the candidate is a member of the American Medical Association, for a brief statement of the candidate's own views on current decisions by the ABPN (such as recertification, internship, etc), and for biographical data, limited to five items (Bd., Apr. '75).

3. By mail ballot, selected Donald G. Langsley, M.D., as APA's nominee for the Association's appointment to the ABPN; selected three members whose names were submitted to the AMA Section Council on Psychiatry for deliberation and forwarding of the final nomination to the chairperson of the AMA Board of Trustees for selection (Ex.C., June '75).

4. Asked the Council on Medical Education and Career Development to study the structural makeup of the ABPN and their involvement in certification and recertification issues, both for later consideration by the Board of Trustees (Ex.C., Sept. '75).

5. Approved recommended procedures for selection and for nomination of APA nominees to the ABPN by an open process that should more closely meet the various professional interests of the membership and recommended that the steps of the process be published annually in *Psychiatric News*, together with adequate information for the education of the membership (Bd., Dec. '75).

6. Endorsed the Reference Committee's recommendation that APA should request the ABPN to create a firm policy that will increase the potential for reciprocity in training for psychiatrists and neurologists (Bd., Dec. '75).

7. Endorsed the Reference Committee's approval to the ABPN for its position regarding allowing credit for British training of candidates for the Board examinations (Bd., Dec. '75).

8. Approved transmittal to the ABPN of the Assembly resolution that graduate psychiatric education be expanded to include responsibility for the clinical care of medically ill patients, as part of graduate psychiatric training leading toward certification by the ABPN (Ex.C., June '75).

9. Endorsed the Reference Committee's recommendation that APA reiterate its belief that this Association should not be a certifying organization, and that the ABPN again be asked to examine candidates for certification in Administrative Psychiatry, on the grounds that they are the best agency to do the job (Ex.C., June '75).

10. Endorsed the Reference Committee recommendation that APA representatives to appropriate bodies (such as the Council of Medical Specialty Societies and others) further explore ways to implement a uniform policy of involvement for the first postgraduate year programs of psychiatric residency training centers (Bd., Dec. '75).

11. Notified the chairperson of the American Psychological Association's Committee on Health Insurance that APA had already discontinued, in advertising the new APA *Psychiatric Glossary*, any specific reference to the definition of medical psychotherapy, that this definition is without any intent to circumscribe psychotherapeutic treatment by other licensed health professionals; and that before the next printing, the definitions of psychotherapy and medical psychotherapy will be reconsidered, taking into consideration the sense of the Executive Committee's discussion as to respective professional roles (Ex.C., Sept. '75).

12. Emphasized the need for each district branch to look at its state or states' Medical Practice Act(s) with a view to needed amendments in the light of licensing of psychologists and others; requested the American Psychological Association, in turn, to ask its local affiliates to note how their local acts may in some way actually or potentially threaten the practice of psychiatry (Ex.C., Sept. '75).

13. Requested the Medical Director to meet with the Executive Director of the American Psychological Association to explore the issues that might be discussed between the two organizations, and to suggest the composition and function of a new ad hoc committee of the two APAs that might work out answers to a series of specific problems affecting relationships between the two Associations (Ex.C., Feb. '76).

14. Deferred making a decision on extending membership on the Joint Commission on Accreditation of Hospital's Accreditation Council for Psychiatric Facilities to the Coalition for Alcoholism Program Accreditation (composed of four nonmedical alcoholism groups) until staff could gather further information (Ex.C., Sept. '75); invited the three APA Councillors and the Program Director of the Accreditation Council to meet with the Board to discuss why they are interested in joining, what the long-range implications of their admission would be, an overview of the decision making process, and anything else that might be helpful (Bd., Dec. '75); voted to admit the Coalition for Alcoholism Program Accreditation to the JCAH Accreditation Council for Psychiatric Facilities (Bd., Feb. '76).

15. Noting that the new name, although cumbersome, has the advantage of being more descriptive of the programs requesting accreditation, approved a name change from Accreditation Council for Facilities for the Mentally Retarded to JCAH Accreditation Council for Services for Mental Retarded and Other Developmentally Disabled Persons (Bd., Feb. '76).

16. Approved reducing the number of members on the APA Committee in Liaison with the American Hospital Association from six persons to four, in order to keep APA's committee membership in balance with the reduced AHA committee, and noted that this can be accomplished by attrition, with two persons rotating off in 1976 (Ex.C., Sept. '75).

17. Considered issues that the Trustees of the Association would like to have studied as the Public Corporation for Mental Health begins to identify problems affecting the interests of APA and that are germane to the charge of the Public Corporation; and encouraged the President, in consultation with the Medical Director, to move implementation in a way that best suits their judgment (Bd., Apr. '75).

18. Approved APA's cosponsoring a session on deinstitutionalization of psychiatric patients at the November 1975 meeting of the American Public Health Association in Chicago, at no expense to APA (Ex.C., June '75).

19. Accepted the invitation of the National Council on Aging to join as one of the cosponsors in their 25th anniversary-year annual meeting at the Sheraton Park Hotel, Washington, D.C., at no expense to APA (Ex.C., June '75).

MEETINGS

1. Approved APA's cosponsorship of a Conference on Psychiatric Classification and Terminology with the University of Missouri, and authorized the Medical Director to receive the funds designated for the conference, to be held in the spring or summer of 1976 (Bd., Apr. '75).

2. Approved APA's participation in the Second Pacific Congress of Psychiatry in 1980 (probably in Honolulu) at no expense to APA (Ex.C., June '75).

3. Endorsed the Reference Committee's recommendation that APA cosponsor the Congress of the World Federation of Mental Health in Vancouver, B.C., Canada, in 1977, with the proviso that this meets with the approval of the VI World Congress Organization Committee, because of concern that it might affect attendance at the Honolulu Congress, Aug. 28–Sept. 3, 1977 (Bd., Dec. '75).

4. Approved holding a conference conjointly with the Institute of Society, Ethics, and the Life Sciences to discuss role conflicts between institutional and individual therapeutic roles of psychiatrists—probably to be held late in 1976 or early in 1977—and authorized a search for outside funding (Bd., Dec. '75).

5. Authorized appointment of an Ad Hoc Committee To Plan a Conference on the Care of the Chronic Mental

Patient, which will be supported in part by the Presidential Fund of Dr. Spiegel (Bd., Feb. '76).

6. After notice of unavailability of rooms for the 1976 annual meeting scheduled for Atlantic City, gave the Meeting Management staff a 1-2-3 priority of Miami, San Francisco, Chicago (Ex.C., June '75); approved rescheduling the meeting in Miami Beach, Fla., as recommended by Meeting Management staff (Ex.C., Sept. '75).

7. Approved Atlanta, Ga., as the site of the 1978 APA annual meeting (Ex.C., Sept. '75).

8. Rescinded the Executive Committee directive of June 1967 that the *American Journal of Psychiatry* print in its March issue the preliminary program of APA annual meetings; approved publication of the preliminary program exclusively in *Psychiatric News*, with a more manageable format (Ex.C., Sept. '75).

9. Endorsed the idea of a postmeeting in Mexico City, but disapproved holding an annual meeting in that city for three principal reasons: there is no district branch there; concern for customs difficulties for attendees and exhibitors; and the fact that many state and federal employees find it difficult to secure permission and funding for out-of-the-country meetings, except for Canada (Ex.C., June '75).

10. Requested the Council on International Affairs to establish a task force to plan a joint meeting with French colleagues, in conjunction with the Program Committee, and also to plan hosting activities and other appropriate activities—possibly in Atlanta in 1978 or Philadelphia in 1979 (Bd., Feb. '75).

11. Authorized the Council on International Affairs to work in conjunction with the Program Committee and the Canadian Psychiatric Association to plan a joint session at the APA annual meeting in Toronto, Canada, in 1977 (Bd., Feb. '76).

MEMBERSHIP MATTERS

1. Approved the Membership Committee's recommendation for 12 reinstatements, and gave tentative approval for 13 others awaiting approval from their district branches; approved 259 recommended nominations for Fellowship in APA, 1 Distinguished Fellow—by transfer from Corresponding Fellow, 1 Honorary Fellow, 9 Corresponding Fellows, 20 Corresponding Members, 1 new General Member-at-Large, and 2 transfers from Associate to General Member—all, as recommended by the Committee on Membership (Bd., Apr. '75).

2. Asked deletion of the interpretation appearing in the Operations Manual that includes the requirement that those Inactive Members and Fellows applying to be excused from paying dues shall have been members for at least 10 years (Bd., Apr. '75).

3. Approved the Membership Committee's recommendation that Members-in-Training who are ineligible for other categories of membership (Associate and/or General Member) be dropped from the APA rolls after five years (Bd., Apr. '75).

4. Approved the interpretation of the Parliamentarian, agreed to by the Membership Committee, that the exemption in Chapter One, Section 5, of the By-Laws (". . . or governmental position that does not require a license") shall include those who work in state hospitals that do not require a license (Bd., Apr. '75).

5. Approved the Membership Committee's recommendation that the policy of requiring Corresponding Fellows and Corresponding Members to bear the cost of the Association's periodicals and mailings not be retroactive and that it apply only to Corresponding Fellows elected in 1974 and thereafter, but asked the Committee on Membership to look into this issue to study the consequences of extending the policy to those elected prior to 1974 (Bd., Apr. '75).

6. Concurred with the interpretation of the Membership Committee and the Parliamentarian that members of APA before 1963 who later joined a district branch could appeal to the Assembly through the Recorder on whether they may legally return to membership-at-large status (Bd., Apr. '75).

7. Received the ruling of APA legal counsel that it is not illegal to require membership in a district branch that does not have the same tax-exempt status as the parent organization, and that members who joined a district branch subsequent to enactment of the 1963 constitutional provision that requires all APA members to belong to a district branch cannot resign from a district branch and remain a member of the national Association; expressed without formal action the hope that any district branch with this question before it would hold in abeyance any action to force any resignation or drop any member who takes issue in one of these areas until it could be decided (Bd., Apr. '75).

8. Adopted the following interpretation of the relevant portions of the Constitution and By-Laws; that members who joined APA prior to May 1964 or members who were directly enrolled in APA at a later time (i.e., who did not join through a district branch, but who subsequently joined a district branch) thereby forfeited the right of at-large membership in the Association and must remain a member in good standing of the district branch in order to retain APA membership (Ex.C., Sept. '75).

9. Accepted the policy stated by the Assembly that no district branch shall admit to membership a psychiatrist who has previously been a member of another district branch, except with the approval of the previous district branch as indicated on the usual transfer form, and that the dues obligation of a member no longer within the jurisdiction of a given branch shall be limited to the dues year during which he moved from the jurisdiction of that branch, plus any dues and assessments owed for all years before he left the jurisdiction of that branch; encouraged district branches to take prompt action on any members in arrears and to notify APA of all their formal membership actions (Bd., Dec. '75).

10. Concurred with the Assembly in approving the Committee recommendation that retired Life Fellows, Life Members, and Inactive Members should have the option of maintaining membership in the district branch where they were professionally active and not be forced to transfer to the district branch of their place of residence (Bd., Dec. '75).

11. Concurred with the Assembly in approval of the recommended procedure for admitting members: when a psychiatrist has been approved for membership in a district branch and in the national Association, the individual will be simultaneously enrolled in both on the first day of the month following the date the approved application is received in the Central Office; and asked that this information be included in the APA *Operations Manual* and the Procedural Code (Bd., Dec. '75).

12. Authorized the Medical Director to seek outside funding to support (with no expense to the APA) a study of the distribution of psychiatrists, relative to population and urban-rural dimensions, in order to supply information for a number of purposes, including input into legislative proposals and backup for a grant submission on continuing education for rural psychiatrists (Bd., Dec. '75).

13. Asked for another legal opinion to ascertain the legality of requesting present Life Members and Life Fellows to pay dues after 30 years of membership; placed a limit of $1000 on the cost of seeking such an opinion; asked appropriate units of the APA to study the presentation of a new by-law to become effective in fiscal year 1978 "that new members of the APA continue to pay dues until they are 70 years old or upon retirement from active practice"(Bd., Feb. '76).

POSITION STATEMENTS AND RESOLUTIONS

1. Requested staff to contact the consulate and embassy to ascertain the extent of Israel's exclusion from UNESCO (Bd., Apr. '75); approved the recommendation that APA join with other associations and respond positively by sending a protest to UNESCO—speaking to the issue that political exclusions have begun to destroy UNESCO and will do so if political decisions are allowed to interfere with international education and scientific and cultural activities (Bd., May '75).

2. Approved publication of the Report of the Task Force on Right to Treatment as a position statement of the APA (Ex.C., June '75).

3. Approved publication of the Report of the Task Force on Lithium Therapy in an early issue of the *American Journal of Psychiatry* (Ex.C., June '75).

4. Approved the recommendation that APA submit to the President's Panel on Research a position paper delineating the psychiatric issues for their consideration—including policies, postures, and concerns of the APA; asked staff to prepare such a paper (Ex.C. June '75).

5. Ratified a telephone vote of the Executive Committee, which approved the proposed position statement on Public Law 93-641, regarding Health Systems Agencies, and asked that throughout the document mental health should be stressed in addition to physical health (Bd., Dec. '75).

6. Approved the recommendation that in those instances wherein reference is made to "black psychiatrist" and "black research workers" in the "Position Statement on the Training of Minority Psychiatrists" (authorized May 1971), the word "minority" should be substituted for "black" (Bd., Dec. '75).

7. Approved the recommendation that the word "public" be dropped from the APA Position Statement on Desegregation of Public Mental Hospitals for the Mentally Ill and Retarded" (authorized December 1963) wherever it applies to hospitals or services (Bd., Dec. '75).

8. Because of the high interest at this time, approved APA's publication of *The Rape Victim*, with the understanding that it would be extensively edited and that the authors would consult with APA legal counsel about the wording (Bd., Dec. '75).

9. Approved in principle the suggested position and report of the Task Force on Ecopsychiatric Data Base and the Council, on fostering conditions and opportunities for each individual to achieve a satisfactory level of life within the individual's cultural and societal context—but asked for suitable editing and simplification before publication (Bd., Dec. '75).

10. Approved the revised, shortened version of the present position statement of the Council on Mental Health Services on Organizational Structure of State Mental Health Programs to make it more current and more useful to the district branches and to the members of the Association (Bd., Dec. '75).

11. Approved the positions expressed by the Council on Mental Health Services as to the different administrative responsibilities of nonmedical administrators and psychiatrists with provision of a procedure for resolving conflicts within institutions where such a pattern may exist; requested appropriate changes in future printings of *Standards for Psychiatric Facilities* (Bd., Dec. '75).

12. Approved and asked for distribution to the Secretary-General of the United Nations, to colleagues in medicine, the behavioral and social sciences, and in the other learned professions of "a position statement by the American Psychiatric Association protesting the resolution of the United Nations General Assembly which holds that Zionism is a form of racism and racial discrimination and dissociating the American Psychiatric Association from further participation in the United Nations 'Decade of Action against Racism and Racial Discrimination' until the resolution is withdrawn" (Bd., Dec. '75).

13. Approved the report of the Committee on Financing Mental Health Care, as modified and approved by the Assembly Executive Committee, as a position statement of APA on the condition that further review may result in altering the language in Section Two, part 3, to read, "Services should include (rather than be limited to) diagnosis and treatment," as being broader language allowing for greater range (Bd., Feb. '76).

14. Approved the "Guidelines for Continuing Education" as a working document, subject to final revision (Bd., Feb. '76).

JULES MASSERMAN, M.D.

Report of the Treasurer

GENERAL: This report is prepared from audited figures for the fiscal year that ended March 31, 1976. Data presented here also appear in the auditor's annual report.

Attached hereto is a statement of financial condition (table 1), and "pie" charts (figures 1 and 2) reflecting revenues earned and functional costs for the fiscal year. This report, together with the statement and charts, will provide the membership with the information they need to assess the operation and financial condition of the Association.

INCOME AND EXPENDITURES: Income and expenditures were budgeted at $4,540,036 for the fiscal year. Income received totalled $4,449,683 or $90,353 under the budgeted amount. Expenditures were $4,772,872 or $232,836 over the budgeted amount.

Income was affected to some degree by recessionary pressures during most of the fiscal year. Short-term investment income was substantially reduced because of the improvement in the money market that caused interest rates to fall to about half those of the previous year. No new grants or contracts were negotiated during the fiscal year.

Expenditures were adversely affected by the inflation that still ravages the economy. Pressures for increased expenditures stemmed from virtually every activity of the Association and prompted strict economy measures.

Operations of the Board of Trustees, the Councils, and the Assembly accounted for 18.4% of the expenditures. This represented a decrease of 4.3% against similar expenditures in the prior fiscal year.

Public Affairs programs required 4.5% of the expenditures, a decrease of slightly less than 1%. Administrative costs amounted to 9.6%, or an increase of 1.6%. Member services accounted for 23.2% of the budget, an increase of .8% over the prior year.

INVESTMENTS: At the suggestion of the Deputy Director for Business Administration, I established the APA Investment Advisory Committee in October 1975. The committee is comprised of eminent financiers in the Washington, D.C., area having expertise in both the money and capital markets. The committee has accepted responsibility for monitoring the APA portfolio (ranging from approximately $2,000,000 to $3,000,000 throughout the year), making recommendations to the Treasurer about sales and purchases of securities, and recommending plans for future investment activities. Based on a recommendation of the committee, the equities portion of the portfolio (approximately $400,000) was transferred from Merrill Lynch to American Security Bank. The remainder of the portfolio (ranging from about $1,600,000 to $2,600,000 throughout the year) is managed directly by the committee. The prime consideration of the committee was the improvement of the quality and diversification of the portfolio holdings. APA realized losses of $101,450 incurred because of earlier declines in the stock market, primarily during 1973 and 1974. It was believed that the fundamental outlook for the stocks of these companies was not sufficiently attractive to warrant their retention.

The return on short-term investments such as commercial paper, certificates of deposit, etc., decreased steadily during the year—from about 8% to the present 5%. Because of this decline in return, it is now more prudent to invest in U.S. Treasury bills and notes than in commercial paper. As of the year end, short-term investments were almost completely in government obligations.

As of April 1, 1976, the APA portfolio (at market value) consists of $600,000 in short-term bonds, $1,795,388 in Treasury bills, $320,000 in savings and loan accounts, and $424,500 in common stocks (17 issues).

The policy of the Association is to employ sound investment vehicles affording the maximum return consonant with safety of capital, i.e., the type of investment a prudent individual would seek. It would appear that the Association's investable funds are now in such securities.

PUBLICATIONS: *Psychiatric News* exceeded budget estimates for income by $5,338. Income had been projected as $711,295, whereas $716,632 was realized. Expenses were budgeted at $719,221, but only $685,426 was expended. *Psychiatric News* operated at a profit of $31,207.

The *American Journal of Psychiatry* produced $780,044 of income but was budgeted to receive only $732,500. Thus, budgeted income was exceeded by $47,544. Expenses of the *Journal* were budgeted at $785,871; however, $790,874 was incurred, or an overexpenditure of $5,003. Instead of the projected deficit of $53,371, the actual deficit was only $10,830.

Hospital & Community Psychiatry operated at a deficit. Income produced was $176,039, and this was $36,961 under that budgeted. Expenses of this journal were budgeted at $367,648; however, only $350,930 was expended.

The Association maintains about 100 publications in its inventory. Of these, only 5 show an annual profit. Sales of these publications exceeded those of the previous fiscal year. In addition, sales exceeded the cost of publishing new books and reprinting others. All of the Association's publications are produced and marketed at prices that assure a return of only printing and distribution costs. The excess of sales over expenses keeps this activity self-sustaining.

The deficit resulting from operations amounted to $221,739, stemming primarily from an understandable reluctance to increase dues in recent years. While APA has gone to the membership 6 times in the past 15 years for added income (an average of one dues increase or building levy every 2½ years), the last substantial increase was six years ago, in 1970. The modest increase of 10% in 1974 did not keep up with inflationary costs and the 1974–1975 fiscal year ended in an overall deficit of $108,188. Since APA was operating at a

This is an edited version of the report presented by the Treasurer to the annual business meeting in Miami, Fla., May 11, 1976.

TABLE 1
Comparison of Fiscal Years 1975–1976 and 1974–1975

Item	1975–1976	1974–1975
ASSETS		
Cash	$ 424,057	$ 3,525
Certificates of deposit	320,000	320,000
Accounts receivable	386,312	487,090
Accrued interest receivable	17,041	31,057
Deferred and prepaid expenses	103,501	72,245
Marketable securities		
Stocks and bonds (at quoted market value)	1,024,500	788,316
U.S. Treasury bills, etc., short-term investments at cost	1,795,388	2,203,554
Notes and advances receivable from the American Psychiatric Museum Association, Inc.	1,757,085	1,757,085
Less		
Valuation reserve	(1,757,085)	(1,757,085)
Land and building (at nominal value)	1	1
Furniture and equipment (at nominal value)	1	1
Total assets	4,070,801	3,906,239
Deduct		
Cash and marketable securities allocated to restricted funds from general fund	366,260	553,354
Total general fund	3,704,541	3,352,885
LIABILITIES		
Accounts payable	21,724	46,890
Due to district branches	46,052	—
Deferred income		
Annual meeting, etc.	122,579	93,281
Advance dues collections (1976–1977)	1,787,393	1,222,906
Accrued expenses and salaries	42,965	25,183
Funds collected and held for Trustees of the Benjamin Rush Foundation	684	21,082
Appropriated for benefit of the American Psychiatric Museum Association, Inc.	—	93,000
Reserve for future expansion and development	1,500,000	1,500,000
Less		
Valuation reserve and marketable securities	(74,584)	(230,374)
Total liabilities	3,446,813	2,771,968
Unrestricted surplus		
At beginning of year	580,917	689,105
Net decrease during the year ended	(323,189)	(108,188)
At year end	257,728	580,917
Total general fund	3,704,541	3,352,885

deficit level of $108,188 going into the 1975–1976 fiscal year, and since expenses outstrip income by more than $120,000 per year, the source of the $221,739 deficit becomes apparent.

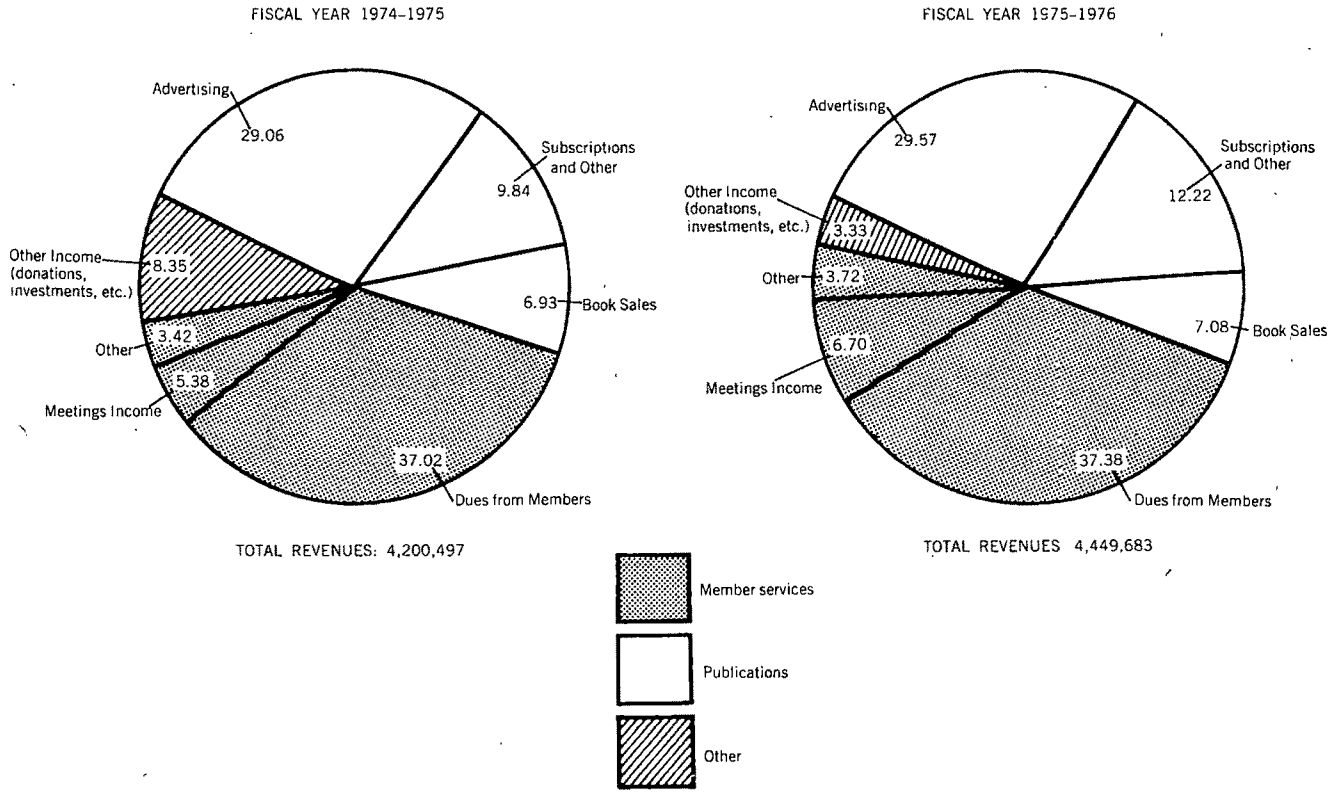
DUES: The dues increase for the 1976–1977 fiscal year seems to have been well received by the membership. The rate of resignations (as of March 23, 1976) is only ½ of 1%, well below the experience of other associations under similar circumstances. Surely, this favorable reception of a substantial dues increase betokens a high morale and sense of common dedication among the members.

During the year the Association had an opportunity to utilize the simultaneous dues billing concept whereby APA dues and the dues of a district branch are billed on the same invoice. The APA dues billing for 1976 included service for 17 district branches and 5 more have indicated a desire to join the system during 1976.

The advantages of the simultaneous dues billing system are 1) the saving to the branches in staticnery, postage, labor, etc., required for individual branch billing, 2) the elimination of correspondence between the branches and APA concerning members' dues paid to each organization, and 3) the elimination of many inquiries by the members themselves. APA receives a small fee representing approximately half of their expenses of billing and collecting dues for both organizations.

ECONOMY MEASURES: In response to economic constraints during the past fiscal year, numerous cost control measures were implemented including the employment of a Deputy Director for Business Administration, elimination of excess expenses in programs, a ceiling on staff raises, renegotiation of publication contracts, a firm resolve that no new programs should be instituted without either the elimination of an existing program or provision for independent funding, and a self-imposed control by the Board of Trustees that the annual budget of APA shall not exceed estimated available revenues without the approval of a two-thirds majority vote of the governing body. Savings in contract renegotiations alone amounted to an estimated $78,000 per year.

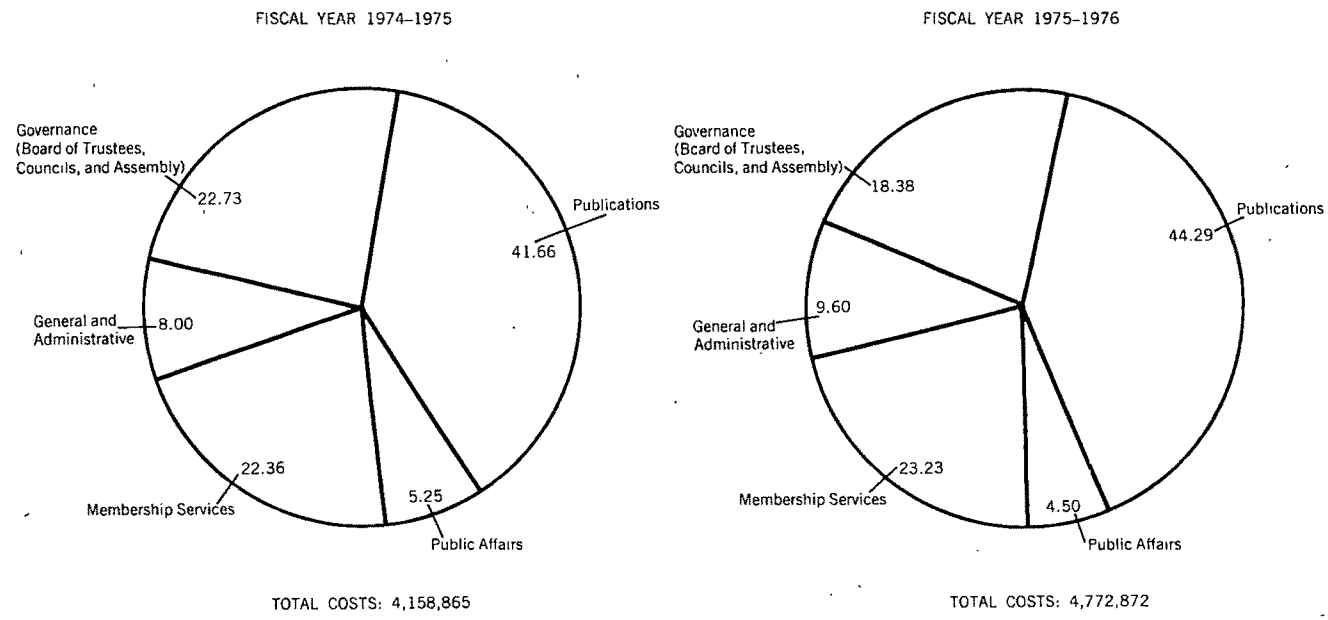
In addition, every effort was made to identify new sources of revenue. Rate schedules were increased for display and classified advertising, charges were instituted for use of copyrighted material except for APA members and educators, reprint schedules were increased, and subscription and service rates were elevated. These rate revisions should bring in an additional $112,000 each year to APA.



EMPLOYEE BENEFITS: APA seeks to maintain employee salaries at a level commensurate with that of the federal government. Thus, a cost-of-living increase was granted to our employees in October.

Workmen's Compensation insurance rates almost doubled from the last fiscal year. The Association's portion of Social Security taxes exceeded that budgeted by a small amount because of the increase in the base amount upon which such taxes are calculated. The base was increased $900 on January 1 by the federal government, and this affected budget estimates during the first quarter of 1976.

BUILDING OPERATION AND MAINTENANCE: Expenses exceeded budget estimates by $11,415. Of this amount, the costs recorded for telephone service exceeded budget estimates by $8,833, reflecting the growing need for quick communication. Water costs exceeded the budget by $457 or 182%. Other items were very close to those budgeted.



CHANGE IN FISCAL YEAR: In June 1975, the Executive Committee voted to change the APA's fiscal year from April 1–March 31 to January 1–December 31, effective January 1, 1977, subject to approval by the Internal Revenue Service. Adoption of the proposed fiscal year would allow adequate time for the auditors to prepare their report for presentation by the Treasurer during the annual meeting, coincide with

FIGURE 1
Comparison of APA Revenues, in Percents*

*Each percentage point represents approximately $41,000.

FIGURE 2
Comparison of APA Cost, in Percents*

*Each percentage point represents approximately $41,000.

the APA's dues-billing period, and conform with the fiscal years of vendors and professional organizations with which APA should compare data.

The details of the total, audited figures for expenses and income are available to the membership for inspection at APA headquarters.

In presenting this third annual report as your Treasurer, I wish to express my sincere appreciation to the Assembly of District Branches, to the Board of Trustees, and to the officers for their continuing and wholehearted support. The same sincere appreciation is due the Medical Director, the Deputy Director for Business Administration, the Comptroller, and the entire staff for their gracious and capable assistance in all matters that I have brought to them during the course of the year.

JACK WEINBERG, M.D.

Report of the Medical Director

THE PAST YEAR has been an extremely active period during which the Association has been engaged simultaneously in considering potential reorganization and coping with a large number of current internal and external issues. Your staff has the task of enabling the decision-making process so that it proceeds as smoothly as possible and the responsibility of implementing decisions that fall within its purview.

I am pleased to report to you that the staff has performed these tasks assiduously, effectively, and with extraordinary devotion. Every effort has been made to economize and to carry out staff responsibilities in a cost-efficient manner. Under the general leadership of the Treasurer and the day-to-day supervision of the Deputy Director for Business Administration, Dr. Jack White, a number of economy moves have saved our members many thousands of dollars. A sizeable dues increase was approved by the Budget Committee and the Board after a report on the fiscal status to the Assembly. The cumulative impact of inflation, recession, the assumption of several new programs, and the lack of recent dues increases necessitated this action. The Assembly, the Board, and the staff are mindful of the need for careful accountability in carrying out all of our respective responsibilities.

The American Psychiatric Association has a broad network of transactions with a large number of associated organizations and institutions. These relationships require consistent reinforcing and reevaluation. In an attempt to consolidate our position and strengthen liaison and communication with our friends in a variety of organizations, my staff and I have met with many groups, including the American Association of Directors of Psychiatric Residency Training, the American Board of Psychiatry and Neurology, the American Association of Chairmen of Departments of Psychiatry, the Liaison Group on Mental Health, the Council of Medical Specialty Societies, the American Hospital Association, the American College of Physicians, the American Bar Association, and the American Medical Association, among others.

One of the major efforts of staff during the past year has been increased and better communication with members. In an attempt to define and delineate how the staff can better assist the membership, the Deputy Medical Directors and I have traveled to many different parts of the country to keep in touch with the opinions of psychiatrist-members. The staff considers this contact with the district branches an important responsibility. Improved service and communication was of prime concern when changes were made in staff functions, and further changes may be necessary to deal realistically with the functional organization of the Association and the accelerated activity of newly organized programs.

Dr. Peter Martin and the Program Committee planned a new program activity for the annual meeting—courses in continuing education. All courses were not only "sold out" but oversubscribed, which emphasizes the demand for this kind of educational experience. We hope that this program will continue to grow as APA takes active leadership in the field of continuing education for psychiatrists.

I have prepared a detailed report with information concerning each of the APA divisions and departments, which is available to any member who requests a copy. I will now briefly call your attention to some new activities.

PUBLIC AFFAIRS

Robert L. Robinson has taken primary responsibility for organizing the new National Commission on Confidentiality of Health Records, Inc. Some 18 national organizations have agreed to become charter members; articles of incorporation have been processed in the District of Columbia. By-Laws have been agreed upon, and Dr. Alfred M. Freedman, past President of APA, has been named president of the new commission.

Mr. Robinson and his division also administered the Conference on Education of Psychiatrists, held in June 1975, and they are presently preparing a substantive report of the meeting and a volume of the working papers, which will be available in late 1976.

We are currently seeking an Assistant to the Director of Public Affairs, whose responsibilities will include staff functions for the new Joint Commission on Public Affairs.

In addition to preparing press releases, arranging interviews, and responding to articles in the public press, this division editorially processed two new task force reports, "Confidentiality and Third Parties," and "Psychiatric Services to Religious Institutions," and one new monograph, *The Rape Victim.*

WOMEN IN PSYCHIATRY, MINORITY AFFAIRS, AND CHILD PSYCHIATRY

Dr. Jeanne Spurlock, Deputy Medical Director, serves as coordinator for activities related to child psychiatry, women, and minority groups. An evaluation of the Minority Group Psychiatry Training Program Fellows is being conducted by assessment of several data sources, including reports on trainees by their supervisors, trainees' evaluations of their programs, and training directors' input concerning the impact of the minority project on their training programs.

Dr. Spurlock continues to broaden her activities, both internal and external, as activities in the field increase. We are pleased to note the formation of the new Council on Children, Adolescents, and Their Families on April 1, 1976. Dr. Spurlock will serve as liaison to this council.

BUSINESS ADMINISTRATION

Dr. Jack White has been with APA for approximately a year and a half, and APA has achieved a much higher level of

This is an edited version of the report presented by the Medical Director to the annual business meeting in Miami, Fla., May 11, 1976.

fiscal responsibility and stability under his leadership. Dr. White and his staff have provided much needed information on projected costs, consulted with the Treasurer, supervised the activities of the business departments, and provided staff support to the Council on Internal Organization and the Budget Committee.

Dr. White, with approval of the Treasurer and Medical Director, established an Investment Advisory Committee last fall, comprised of three financiers from Washington, D.C., with expertise in money and capital markets. This committee has responsibility for monitoring the APA portfolio and making recommendations on sales and purchases of securities; it has provided invaluable assistance to the Treasurer.

In the budgeting process for 1976-1977, emphasis on identifying new sources of revenue and reducing expenses resulted in new printing arrangements for APA publications, at considerable savings. Also, rates charged by publications for copyright privileges, reprints, and advertising have been increased.

Dr. White supervises the following business departments: Accounting and Fiscal, Administrative Services, Meetings Management, Publications Services, and the VI World Congress of Psychiatry. Under his supervision the methodology for an APA-wide employee salary review is being completed. A systematic review and revision of salaries will be forthcoming.

Dr. White has also worked intensively on the malpractice program with the Committee on Insurance and the Joseph A. Britton Agency. APA reluctantly accepted a rate increase because we could not secure alternative means of providing an equally sound program for our members. Dr. White and his staff have attempted to answer each member's concern or complaint on an individual basis, explaining the reasons for the increases and APA's position that it cannot with confidence recommend any other malpractice program at the present time. Because of the membership's concern over the malpractice issue, the staff is deeply involved in seeking the best possible mechanism to deal with this very pressing matter.

During the past year we conducted a test run on the dues billing system. The dues year began on January 1, 1976, and 17 district branches participated in the simultaneous dues billing system. Four others will run special billings for a partial year during 1976. Thus, assuming that all on the system remain, 21 branches or more will be participating in the simultaneous dues billing system in 1977.

By the end of the fiscal year (March 31, 1976) 50% of the dues billed in January 1976 had been collected. Although a number of our members have found the increase a hardship, the overall response has reflected understanding and support of the Association's fiscal status.

Dr. White is also working on implementing the Board's action to place the APA fiscal year on a January to December basis that will parallel dues billing, which now takes place on January 1. It is anticipated that this changeover will take place in January 1977.

ADMINISTRATIVE SERVICES

Charles B. Kurta was employed as Chief of the Administrative Services Division in July 1975, replacing Rodney A. Rollo, who retired. His areas of responsibility include personnel administration (at present there are 99 permanent employees in the Central Office), office services, building maintenance, security, communications, insurance risk management, and shipping room functions. The division's responsibility for staff liaison with the membership in the area of insurance matters and retirement plans is becoming increasingly important.

During this fiscal year, the division provided service for 196 in-house meetings; it also processed some 212,231 pieces of outgoing mail, a sizeable increase over last year and a significant indicator of the Central Office work load. The volume of incoming mail has reached a peak of 1,386 pieces per day (or 382,692 during the past year), and careful attention is required to open, sort, and distribute this material correctly.

PEER REVIEW AND COMPREHENSIVE HEALTH PLANNING

Dr. Donald W. Hammersley has begun to coordinate the activities of Dr. Richard Dorsey, whose contract with APA began on April 1, 1976. Dr. Dorsey will serve as field consultant to the district branches out of the newly formed Office of Peer Review. He will visit district branches that have peer review components in the beginning stages of development, as well as those which are more experienced, in order to provide consultation services and reports that will be shared around the country.

Also under Dr. Hammersley's direction is the Office of Comprehensive Health Planning, headed by Mr. Sam Muszynski. This office was established in September 1975 so that APA might be able to respond effectively to all aspects of P.L. 93-641, the National Health Planning and Resources Development Act of 1974. A packet was prepared and sent to the district branches to explain the purposes of the act in order that states might seek appropriate inclusion of mental health components in all planning for health service agencies.

Dr. Hammersley and his staff continue their support of many other activities, and serve as liaison and secretariat to the Reference Committee, the Councils on Professions and Associations and Mental Health Services, the Commission on Standards of Practice and Third-Party Payment, the Ad Hoc Committee on Interprofessional Services, and the Falk Fellowship Program.

STAFF COORDINATION WITH THE ASSEMBLY AND DISTRICT BRANCHES

The staff continues to service and correspond with Assembly officers and related components (the 7 area councils and the 72 district branches) and to coordinate the preparation of agenda and backup material for the various meetings throughout the year. As the Assembly takes on an even more responsible and authoritative role in the affairs of the Association, the activity of this office increases. Although Dr. Henry Work, Mrs. Anne Whinnie, and other staff have done an excellent job in carrying out staff responsibilities related to the Assembly's expanded functions, it is obvious that some increase in staff will be required during this fiscal year in order to carry out the mandates of the Assembly.

PROFESSIONAL AFFAIRS AND THE OFFICE OF EDUCATION

Dr. Henry Work, in his role as Deputy Medical Director, provides leadership and consultation to a variety of activi-

ties, including the Hospital & Community Psychiatry Service, the Consultation and Evaluation Services Board, the Councils on Medical Education and Career Development and Research and Development, the APA Program Committee, the VI World Congress of Psychiatry, and the Assembly of District Branches. He also directs the current educational effort, and this year Dr. Work provided important liaison to the search committee (appointed by the Council on Medical Education) to locate a new Director of the Office of Education. It is hoped that in the coming year, as the Assembly of District Branches requires additional services from Dr. Work and staff, some of these activities might appropriately be transferred to the new Director of the Office of Education, Dr. Carolyn Robinowitz. In carrying out those responsibilities and others, Dr. Robinowitz will assume the title of Deputy Medical Director.

During the coming year there will be increased staff emphasis on the development of continuing education programs within district branches, and we anticipate that Dr. Robinowitz will be visiting many states to provide encouragement and help in this expanded activity.

A system has been instituted to distribute information to district branch continuing education personnel, beginning with a book of guidelines about the development of continuing education programs. It is hoped that the program related to the new continuing education requirements for APA membership will be operative by July 1976. The requirements essentially parallel those used by the American Medical Association for its Physician Recognition Award, and this office is working with the AMA to ensure maximum flexibility in interpretation of the category system.

Preparations for the Psychiatric Knowledge and Skills Assessment Program III have been completed. A bulletin of information has been mailed and the program schedule is as follows: program materials will be mailed to registrants on June 15; answer material is to be returned on September 10 for central scoring; and performance data will be mailed on November 15. There are some innovative aspects in the program, including a recorded patient interview for one of the patient management programs and complex multiple branching questions concerning patient management.

Dr. Howard Kern's contributions, not only to the APA continuing education program but also to the education of nonpsychiatric physicians around the country, have been numerous. The Physician Education Project has flourished under his direction, continuing education is receiving increasing support, and he leaves us with a staff capable of operating the current program and implementing innovations.

MEMBERSHIP SERVICES AND STUDIES

The Membership Division and the Manpower Division were merged during 1975 and placed under the leadership of Dr. Lee Gurel. The positive impact of this decision will become increasingly evident in improved services to members in the form of better communication. This division also conducted the 1976 balloting with meticulous care.

Of particular interest is the Census of Residents, begun in September 1975. As of April 1976 only two programs had not yet reported. Coding and processing have been difficult in view of the shift of some training programs to 4 years.

Plans are under way for a 1977 *APA Membership Directory* early in that fiscal year and for what is expected to be the 1978 edition of the *Biographical Directory*, published at 5-year intervals.

MEETINGS MANAGEMENT

In addition to its responsibility for the annual meeting, the Institute on Hospital & Community Psychiatry, and many other continuing functions, this department is now involved in planning for the VI World Congress of Psychiatry and helped with planning for the Joint Caribbean Congress of Psychiatry held in Puerto Rico, May 15–18, 1976.

I would like to thank Dominic J. Deriso for his excellent management of this department over the past 6 years. Mr. Deriso will retire in July and Mrs. Kathleen Bryan will become director. Mr. Deriso has exhibited excellent judgment throughout the years in recommending sites for the annual meetings and has worked tirelessly to ensure that this department is administratively sound.

VI WORLD CONGRESS OF PSYCHIATRY

APA accepted the role as host of the VI World Congress of Psychiatry, to be held in Honolulu in August 1977. Staff headquarters are located at the APA Central Office.

First and second Congress announcements have been printed in four languages (French, Spanish, German, and English). A contract for travel arrangements has been signed with Group Travel Unlimited and a travel brochure has been prepared. Funding for the Congress has been sought and some monies have become available. In addition, it is expected that a special grant will be obtained from the Department of Commerce to help finance this activity.

A preliminary program will be available for distribution at the APA annual meeting, and the Organizing Committee, Scientific Program Committee, and the Finance Committee will meet during the annual meeting in Miami Beach.

LIBRARY

The library maintained a good level of activity, attempting to continue to provide a full range of information services to the APA Central Office and to members. An exhibit entitled "American Psychiatry, 1789-1909" opened in December 1975, and the library has received requests for copies of the exhibit materials from other mental health organizations. This exhibit represents the first major presentation of the Library/Archives.

Over 700 new books were added to the library this year, and we maintain over 225 active subscriptions to periodicals. APA was accepted as a MEDLINE Center in January 1976, and the system, which involves a computer terminal at APA connected to a data base maintained by the National Library of Medicine, is now in operation. This information retrieval service will expand the library's reference and current awareness programs.

JOINT INFORMATION SERVICE

The chairperson of the JIS Executive Committee reported to the Board of Trustees in April 1976 on activities of this division. It is gratifying to note the continuing originality and high quality of JIS publications. Two significant studies, one on private practice and the other on "indigenous" helping agencies, were published this year. The present work on a volume dealing with the needs of the elderly mentally ill promises to be similarly significant.

Mr. Raymond Glasscote and his staff are making every effort to identify sources for necessary outside funding to augment the JIS budget. They are now seeking support for studies on the current status of primary prevention in mental health. We are grateful for the continued leadership and cooperation of the National Association for Mental Health in this joint effort.

GOVERNMENT RELATIONS AND JUDICIAL ACTION

The new Joint Commission on Government Relations became operative in 1975 and has developed close ties with legislative representatives in the district branches as the legislative network gains strength, sophistication, and organizational integration.

The 5th Institute on Government Operations, held in March 1976, was successful, and the legislative representatives had a chance to develop some relationships with Senators and Congressmen from their states.

More than 50 pieces of legislation are currently being monitored and acted upon by the Division of Government Relations under the leadership of Mr. Caesar Giolito and his staff; in addition, APA testified before Congress 14 times during the past year.

This division also serves as secretariat for the Liaison Group on Mental Health (I served as chairperson during the past year). This group, composed of representatives from various organizations working in the mental health field, is currently attempting to assess whether or not it is possible to formulate a common mental health position on national health insurance.

Stanley I. Bregman, of Bregman, Abell, Solter & Kay, began serving as a part-time legal/legislative consultant to APA on January 1, 1976. His primary administrative relations are with Dr. Hammersley, but he may be called on by other staff. Mr. Bregman also continues to serve the Washington Psychiatric Society in this capacity.

Mr. Bregman's recent activities include arranging with the Republican and Democratic Platform Committees for the appearance of an APA representative and exploration of the new CHAMPUS policies on reimbursement, which has involved contact with Congressional and Department of Defense staffs.

Last year I called to your attention the work of the Commission on Judicial Action. The commission has now requested each district branch to develop its own committee to work in this area so that the work of the commission can be facilitated by contact with knowledgeable people in each state. In addition, this year we will add to the staff an attorney with expertise in mental health and the law who will work under the aegis of the commission and be responsible for writing briefs for the Association that may be filed in court cases of national concern.

PUBLICATIONS

The increase in the number of manuscripts submitted to the *American Journal of Psychiatry* has reached proportions that concern the Editor, Dr. Francis J. Braceland, and the staff. There was a 14% overall increase in calendar 1975, due mainly to a 16% increase in unsolicited (as distinguished from annual meeting) papers. This has increased the workload on staff considerably.

Among the outstanding overview and other special articles in 1975 were "Psychiatry and the Elderly" by Robert Butler, M.D., "The Madness of Art" by Leon Edel, D. Litt., and "Maintenance Therapy in Psychiatry" by John Davis, M.D.

Mrs. Evelyn Myers, Managing Editor, is also involved in activities concerning health insurance coverage of mental illness; she has continued her work on the report of the APA Committee on Financing Mental Health Care, which will be published shortly.

Under the leadership of the Editor of *Hospital & Community Psychiatry*, Dr. Donald W. Hammersley, staff has given considerable attention this year to ways of increasing income and controlling costs. We are confident that the financial picture for this journal will be considerably improved in the year ahead. Circulation now stands at 18,500, with a steady increase in individual subscribers. The staff and Editorial Board have also been diligent and creative in seeking new ways to publicize the *Hospital & Community Psychiatry* journal and to make its content even more attractive and interesting to a diverse and large group of readers.

In the context of fiscal accountability, *Psychiatric News* changed printers effective February 1976 with the hope of a 16% reduction in printing costs. Revenues continue at a high level. In March, William Byrd Press, the new printer, advised that the U.S. Postal Service office in Richmond, Va., would begin providing "preferential" treatment for *Psychiatric News* that should expedite delivery throughout the country.

From time to time, members are critical of particular reports, and occasionally *Psychiatric News* has been strongly criticized. In my judgment, however, the newspaper continues to be well received by the overwhelming majority of APA members and other readers.

PUBLICATIONS SERVICES

To provide more efficient supportive services to APA's publications, Dr. Jack White has reorganized this division. At present, all advertising in journals, circulation matters, printing, and promotion are handled by this staff. In addition, transfer of advertising, reprint, and circulation billing to accounting and *AJP* reprint permission to Publications Services is planned during 1976–1977.

It is interesting to note that advertising income for fiscal year 1975–1976 is up 12.2% over last year; subscription income is up 12.6% (due to rate increases for subscriptions).

Because of insufficient staff time, promotion activities have been necessarily limited. However, plans are being made to discuss the development and implementation of a promotion program for publications. A redesigned APA Publications List was made available in May.

CLOSING REMARKS

This has been a "key" year in the history of the Association, beginning in March 1975 with the Key Conference. In June, the staff had a "Mini-Key" Conference to discuss recommendations emanating from the Report of the Key Conference Task Group No. 5 on Staff Roles. This began a process of looking at the interfaces among various departments, potential conflicts that exist in staff activities, and the manner in which staff relates to the membership, and was followed by "diagnosis" of staff functions and activities as well as the manner in which they can best be carried out. Staff is planning other meetings to continue discussions of organiza-

tion along more functional lines. I have met with small department groups to facilitate this planning.

Staff has also been involved in the preparation and distribution of the many documents that have been produced as a result of the Key Conference: the report itself, the many reports of the Assembly Task Force on the Key Conference, the Board's Ad Hoc Committee, and the Joint Conference Committee on the Key Conference Recommendations. I am sure that most of you are aware of the many versions of the Constitution and By-Laws that have been produced and the analyses, legal opinions, and other documents that have been sent to the district branches for study.

This has been an extraordinary year—challenging, occasionally tumultuous, and educational. I am grateful to the Board of Trustees, the Reference Committee, the members of the Assembly of District Branches and its Executive Committee, the district branches, and the entire membership for their continued support and confidence in the staff.

MELVIN SABSHIN, M.D.

Report of the Speaker

THE WORK OF this past year has been directed at implementing the recommendations of the 1975 Key Conference.

NEW PROCEDURAL CODE OF THE ASSEMBLY

The Assembly's Committee on Planning and Development and the Task Force on Key Conference Recommendations proceeded with the revision of the Assembly Procedural Code. In order to make the Assembly more truly representative of the membership, provisions were made for a more broadly based nominating process and more uniform election procedures of delegates and alternate delegates (now to be known as district branch representatives and deputy representatives), including ballot distribution to every member and the possibility of recall of any elected representative. Area representatives and area deputy representatives are being limited to two consecutive terms, with reelection being permitted only after a three-year lapse. Provisions for voting, including splitting of the number of votes to which any district branch representative is entitled, were modified so that the vote could be most representative of the wishes of the members of the district branch. The functions of Assembly committees, including the Executive Committee, were clarified, emphasizing the importance of responsibility and accountability. The new Procedural Code was adopted at the November 1975 meeting of the Assembly, and area councils and district branches were enjoined to conform their respective procedural codes or by-laws to it by May 1977.

Constitutional and by-law changes were also proposed for the Association in order to shift more specific policy-making functions to the Assembly. These were eventually modified through collaboration with the Ad Hoc Committee on the Key Conference Recommendations of the Board of Trustees and subsequently collated by the Committee on Constitution and By-Laws for presentation to the membership.

ACTION PAPERS FROM DISTRICT BRANCHES AND AREA COUNCILS

Specific action was taken on many items under the following categories:

Right to Treatment

The report of the APA Task Force on the Right to Treatment was carefully reviewed, and amendments to the section dealing with the right to refuse treatment were proposed based on the Association's main concern with clarifying the existing and growing need for implementing and enlisting support for the right to treatment and on the understanding that the right to refuse treatment is legally vouchsafed and need not be part of the statement about the right to treatment.

Financing of Mental Health Care

The report of the APA Committee on Financing Mental Health Care was approved in part; the remainder was the subject of a joint meeting of that committee and the Assembly Task Force on Delivery of Mental Health Services for purposes of refining the document, stressing the feasibility of full and equal coverage of psychiatric conditions under proposed national health insurance, and reaffirming the desirability of retaining multiple models of delivery of mental health care.

Continuing Medical Education

Several actions papers were concerned with the "guidelines" as prepared by the Council on Medical Education and Career Development. Questions were considered concerning accrediting agencies, acceptable programs, date for the submission of data regarding fulfillment of continuing education requirements for continued membership in the Association, and the specific continuing education needs of psychiatrists. It was proposed that the current guidelines be used for purposes of accumulating presently needed credits, and two members of the Assembly were appointed to the Subcommittee on Continuing Education of Psychiatrists, a component of the Council of Medical Education and Career Development, for further clarification of standards and methods.

The Community Mental Health Center

The role and responsibility of psychiatrists as differentiated from other disciplines will be considered by an Assembly task force to study problems encountered in different areas by various district branches. Appropriate changes in future printings of *Standards for Psychiatric Facilities* will also be made by the Council on Mental Health Services.

Relationship Between APA and Pharmaceutical Companies

Concern with ethical considerations and financial implications resulted in the establishment by the Board of Trustees of a Task Force on Interface between Psychiatry and Industry, on which two members of the Assembly will serve.

The Chronic Psychotic Patient: A Silent Majority

The need for critical studies of current programs for new research and for coordinated efforts to obtain adequate funding, together with a recommendation by the Assembly that the establishment of a commission on a national level be considered, resulted in making this subject a priority item for the Council on Emerging Issues.

This is an edited version of the paper presented by the Speaker of the Assembly of District Branches to the annual business meeting in Miami, Fla., May 11, 1976.

Establishment of the Council on Children, Youth, and Their Families

An action paper suggesting that the former Commission on Childhood and Adolescence was inadequate to implement potential and actual APA responsibilities on behalf of young people or to make optimal use of APA's child/adolescent psychiatrists and recommending that a separate council be established resulted in the approval by the Board of a Council on Children, Adolescents, and Their Families with a specific charge.

JOINT COMMISSIONS

Commission on Judicial Action

Continued and improved exchange between this commission and the district branches has proven valuable and effective—two members of the Assembly participated in the work of the commission. At the request of the commission, the Assembly approved a resolution to set up commissions on judicial action in district branch areas to serve as intermediaries with the national commission to seek collaboration with the Commission on the Mentally Disabled of the American Bar Association and the local bar associations where this can be productive.

Joint Commission on Government Relations

This has become a very important component of the Association, with its chairperson being appointed jointly by the President and the Speaker and its membership consisting of representatives from the seven area councils. It collaborates with the Division of Government Relations in the APA Central Office and with the district branch legislative representatives. It is doing a remarkable job in keeping the Board, the Assembly, and the membership informed of developments in national, state, and local legislation pertinent to mental health and in offering the Association's informed advice to government representatives.

Resolutions on legislative and judicial intrusion into psychiatric practice, confidentiality of the psychiatrist-patient relationship, and questions arising about psychiatric services in nursing homes and about psychiatry as primary care have been referred to this joint commission.

CONSTITUTIONAL COMMITTEES

An Assembly-initiated constitutional amendment to Article II, Section 1, "to act as an advocate for patients and those actually or potentially making use of mental health services," was referred to the Committee on Constitution and By-Laws and submitted by this committee to and approved by the Board.

Questions regarding the requirement to state whether an applicant for medical licensure in certain states has "ever been in psychotherapy" were referred to the Ethics Committee. This committee was also asked to explore the inclusion of alternative or additional actions to be taken in situations where unethical conduct by a member is established. The Assembly further suggested that a copy of *The Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry* be given to each new member of the Association.

A proposed pamphlet on APA functioning, produced by the Committee of Residents, was approved in principle and, through the Board, was referred to the APA and Assembly Membership Committees for revision and final editorial review.

BOARD OF TRUSTEES

Throughout this eventful year the Assembly's advice and consent was actively sought by the Board and eagerly offered by the Assembly. The Assembly also appreciated the effective presence and contributions of the officers and Trustees of the Association at its meetings. The help and guidance of the Central Office has continued to be invaluable and indispensable.

MILTIADES L. ZAPHIROPOULOS, M.D.

Report of the Speaker-Elect

THE YEAR AHEAD will probably be one of unusual transition, one in which the Assembly and the membership will consider a drastic modification of our past structure. While change is mandated by our growth, the exact form of such alteration is subject to reasonable disagreement. A variety of value systems is represented among us, each of which conveys rightness and wrongness from a different perspective. The inherent pluralism of our membership requires a devotion to and a recognition of our professional purpose and function. As I have said before, the essence of a profession is personalized service based on specialized learning ethically applied. I adhere to that concept as the foundation of the profession and its representative structure.

We live in a dynamic world in which our organization has a legitimate guild purpose as well as a leadership role in determining the use of our services for the greatest good. While we must devote the most punctilious attention to our needs as a guild, we must be sufficiently aware and flexible to avoid becoming birds in a "guilded" cage, inhabitants of a ghetto world where we can communicate only with each other in disputatious anger and frustration.

Attention to structural organization and devotion to a profession are not necessarily a vice, and internecine and "siblicidal" (a word coined to replace "fratricidal") warfare in the name of a school of thought or in furtherance of other causes is certainly not a virtue. This is not to say that past practices, rules, and ideas are infallible; the immense effort by the psychiatric leadership in the last year bespeaks the contrary.

Democracy is not merely a word or a structure; it is a process dependent upon the participation by the individual member in conformance with the role both approved by him/her and then allowed to or spelled out for him/her. The purpose of a new Constitution is to facilitate this process in a systematized and orderly fashion; this purpose will be met only to the degree that individual members conform to and participate in the process that they approve.

The Assembly will be particularly affected by such change, as the various proposals confer both greater responsibility upon the delegates and greater constraints upon the manner in which they are chosen. The Assembly has become more important not because of its inherent goodness but because one cannot have an annual town meeting of 22,000 people and one cannot confer unchecked power on a small group whose members are often determined by the vagaries of name recognition. Equally important is balancing the need for continuity with the need for flexibility, innovation, and accessibility. Similarly, policies governing complex issues cannot reasonably be determined by the individual unless that individual is well informed as to the issues, the fact base, and the merits of alternative solutions. The more complex the issue, the greater the need to delegate to a group designed for this purpose. It has been said that new burdens will fall to the lot of the Assembly; this is only partly so. The true burden will be that of the individual member and his/her responsibility to participate at the district branch level where the possibility of influence is maximized.

In the course of my years as a migratory psychiatrist with a variety of professional careers, I have found most stimulating and exciting the immense spectrum of peoples and roles encompassed within our field. Psychiatry is a medical specialty with the broadest perspective in medicine, the most humanistic and concerned of human endeavors, and the most learned in the sense that so much information arduously accumulated by the efforts of the human intellect is applicable to our purposes.

With only the most tenuous ties of our profession to bind us, we reflect an amazing array of cultures, nationalities, regions, races, sexes, sexual practices, political beliefs, religious and philosophic orientations, and professional roles. We are truly international in purpose, practice, and constituency. We are also the inheritors of the noble philosophy of the New World, which sought to welcome everyone to these shores. I recognize that the society in which we live has failed grievously at times in this regard, but that should not deter us from opening the doors as a profession to all qualified, both from within and from without, and this we have done. With this heritage, we cannot afford to dissipate our professional blood unnecessarily on the sacrificial altar of other identifications and causes.

From another vantage point, psychiatry can be viewed as a vital, living organism which we hope will never reach maturity, for maturity implies the end of growth and the onset of senescence. Our potential for continuity and relevance depends on constant evolution and adaptation to changing needs, pressures, knowledge, and goals.

Let us therefore seek unity amidst our pluralism. Let us act with compassion, upon knowledge and experience, and without prejudice or prejudgment, but let us not ignore the need for reasonable judgment and appropriate discrimination. Let us attempt to speak for all, while viewing with skepticism those who would speak for some. Let us protest when the voices of the ill-informed, the dogmatic, and the self-serving raise their cry in the halls of the legislatures and the offices of government. Let us lead by deed and not by word. Let us recognize that image and acceptance must be based on individual and group behavior, participation, and accomplishment at all levels and in all places. We cannot withdraw to a self-imposed ghetto of injured professionalism.

To these principles and goals I hope to direct my energies as Speaker, not as a leader but as a moderator and coordinator with those others who share the responsibility for carrying out the purposes of the American Psychiatric Association.

IRWIN N. PERR, M.D., J.D.

This is an edited version of the report presented by the Speaker-Elect of the Assembly of District Branches to the annual business meeting in Miami, Fla., May 11, 1976.

Report of the Committee of Tellers

THE COMMITTEE OF TELLERS met at APA headquarters in Washington, D.C., on April 8, 1976. Committee members present were Dr. Donald McKnew and Dr. Leon Cytryn; Dr. Eugene Hargrove, committee chairperson, had unexpectedly been called out of town. Dr. McKnew served as acting committee chairperson. Rulings were made on irregular ballots and votes noted in the final report presented to the Board of Trustees on April 11, 1976.

There were 20,463 eligible voters. Of these, 11,139 (54.4%) returned ballots. In the three areas in which a Trustee was being elected, Areas I, IV, and VII, 56.1%, 61.1%, and 58.8%, respectively, of the eligible voters returned ballots.

It was noted that 17 voters returned ballots in unofficial envelopes; and 7 returned ballot envelopes without ballots in them. There was only one request for ballots from a member who did not receive them; a second request was from a nonmember. Ballots were not mailed to the member, in accordance with guidelines for a totally secret election.

On April 8, 1976, the Committee of Tellers certified the following individuals as elected: Dr. Charles B. Wilkinson, Treasurer; Dr. Nancy C. A. Roeske, Trustee-at-Large; Dr. William B. Spriegel, Area IV Trustee; Dr. David Starrett, Area VII Trustee.

The Committee of Tellers further certified that in three offices, President-Elect, Vice-President, and Area I Trustee, no candidate obtained the mandated 40% plurality of the votes cast as required in the *Operations Manual* of the Board. A runoff election between the top two candidates in each office was held and the following individuals were elected: Dr. Jack Weinberg, President-Elect; Dr. Alan A. Stone, Vice-President; Dr. Ben W. Feather, Area I Trustee.

In addition, the Committee of Tellers certified that the following amendments to the By-Laws were approved: Chapter 3, Section 3; Chapter 8, Section 5; Chapter 9, Section 1; Chapter 10, Section 1.

In every instance, percentages of those in favor or opposed were found to conform to the requirements contained in the Constitution and By-Laws for the adoption of amendments.

The Committee of Tellers also certified that the two referenda by petition were approved. Again, percentages of those in favor were found to conform to the requirements contained in the Constitution and By-Laws for the adoption of referenda.

EUGENE A. HARGROVE, M.D.

This is an edited version of the report presented by the Chairperson of the Committee of Tellers to the annual business meeting in Miami, Fla., May 11, 1976.

Report of the Membership Committee

DURING 1975, the Association admitted the following new members: 476 Members-in-Training, 25 Associate Members, and 919 General Members for a total of 1,420 new members. Further, 63 members resigned, 25 members were dropped from the Association for not being in good standing in a district branch, and 104 members were dropped for nonpayment of dues. The names of the 175 members who died during the year are inscribed in the Necrology Register. Total membership losses were 367.

A total of 655 members were advanced to General Member status from Member-in-Training or Associate Member status. On recommendation of the Committee on Membership, the following actions were taken by the Board of Trustees at its meeting on May 9, 1976: 206 General Members were advanced to Fellow status, 2 Corresponding Fellows and 10 Corresponding Members have been admitted to membership, 5 General Members-at-Large were admitted, 16 members joined the ranks of 50-year Life Fellows and Life Members, 146 Fellows became Life Fellows, 57 General Members became Life Members, and 36 members were transferred to the status of Inactive Membership.

In addition, the Board of Trustees approved the following transfers in membership status: 1 Fellow to Corresponding Fellow, 1 Corresponding Member to Corresponding Fellow, and 7 transfers to Corrresponding Membership.

As of March 31, 1976, the Association had 22,426 members: 1,413 Members-in-Training, 976 Associate Members, 13,079 General Members, 4,430 Fellows, 313 Life Members, 1,237 Life Fellows, 126 Corresponding Members, 203 Corresponding Fellows, 26 Distinguished Fellows, 33 Honorary Fellows, and 590 Inactive Members. This total of 22,426 compares to 21,360 a year ago for a net gain of 1,066 members.

LAURA E. MORROW, M.D.

This is an edited version of the report presented by the Chairperson of the Membership Committee to the annual business meeting in Miami, Fla., May 11, 1976.

1975 Annual Report of the American Board of Psychiatry and Neurology, Inc.

OFFICERS AND MEMBERS OF THE BOARD

AT ITS ANNUAL MEETING on October 5, 1975, the Board elected the following officers: Dr. Milton Greenblatt, President; Dr. David B. Clark, Vice-President; Dr. Chester M. Pierce, Secretary; and Dr. Thomas W. Farmer, Treasurer.

The following members were elected to the Board: Dr. Donald G. Langsley, who had been nominated by the American Psychiatric Association to replace Dr. Harvey J. Tompkins; Dr. S. Mouchly Small, who had been nominated by the Section on Psychiatry of the American Medical Association to replace Dr. Robert L. Stubblefield; and Dr. Patrick F. Bray, who had been nominated by the American Neurological Association to replace Dr. William M. Landau.

The 1976 Directors of the American Board of Psychiatry and Neurology, Inc., are as follows:

Nominated by the American Medical Association: Dr. S. Mouchly Small (term expires December 1980), Dr. Richard M. Steinhilber (term expires December 1977), Dr. James N. Sussex (term expires December 1979), Dr. Thomas R. Johns (term expires December 1979), and Dr. Robert J. Joynt (term expires December 1976).

Nominated by the American Psychiatric Association: Dr. Milton Greenblatt* (term expires December 1976), Dr. Chester M. Pierce* (term expires December 1979), Dr. Donald Langsley (term expires December 1980), Dr. Marc H. Hollender (term expires December 1977), and Dr. Alfred M. Freedman (term expires December 1979).

Nominated by the American Neurological Association: Dr. Melvin D. Yahr (term expires December 1979), Dr. Patrick F. Bray (term expires December 1980), Dr. David B. Clark* (term expires December 1976), and Dr. Thomas W. Farmer (term expires December 1977).

Nominated by the American Academy of Neurology: Dr. Audrey S. Penn (term expires December 1979) and Dr. Dewey K. Ziegler (term expires December 1979).

EXAMINATIONS

Part I

At the Part I examination (written) on April 21, 1975, 1,783 psychiatrists were tested; 1,163 (65.2%) passed and 620 (34.8%) failed. Of the 456 neurologists tested, 292 (64%) passed and 164 (36%) failed. (See table 1 for the number of candidates declared eligible and notified for Part I in 1975 and table 2 for a comparison of these figures with recent years.)

This is an edited version of the report presented by the American Board of Psychiatry and Neurology, Inc., to the American Psychiatric Association, May 11, 1976.

*These Directors are serving their second term of four years and are not eligible for reappointment.

Part II

Statistics on Part II examinations administered in 1975 and 1976 to date are listed in tables 3–12.

The Part II examination schedule for 1976–1977 includes examinations in Minneapolis on June 21–22, 1976, in Chicago on October 18–19, 1976, in Washington, D.C., on April 18–19, 1977, and in Kansas City, Mo., on June 6–7, 1977.

CHILD PSYCHIATRY

Members of the 1976 Committee on Certification in Child Psychiatry are: Dr. John F. McDermott, Chairperson; Dr. Jeanne Spurlock, Vice-Chairperson; Dr. Irving Philips, Secretary; Dr. Richard Ward; Dr. Barbara Fish; and Dr. Joseph Green. The Board recently approved the committee's nomination of Dr. Norman Bernstein, Director of Child Psychiatry Training, Massachusetts General Hospital, Boston, Mass., to replace Dr. Fish, whose second term expires in February 1976.

On April 4–7, 1976 the committee held a conference for approximately 121 child psychiatry training directors at the Sil-

verado Country Club in Napa, Calif. The conference focused on the "Roles and Functions of Child Psychiatrists," a report from the Project on Certification in Child Psychiatry. The report is the result of a joint three-year study by the committee and the Center for Educational Development of the University of Illinois College of Medicine for the purposes of 1) developing more valid and reliable procedures for certifying competence in child psychiatry, 2) generating data that would be of assistance to training directors in increasing the efficiency and effectiveness of child psychiatry training programs; and 3) serving as a pilot for a larger study in general psychiatry to be initiated subsequently by the American Board of Psychiatry and Neurology, Inc. The study was funded by the Grant Foundation, the Maurice Falk Medical Fund, and the Ittleson Family Foundation. Copies of the report are available from the Board's Executive Office at $6.00 per copy.

BOARD POLICY DECISIONS AND ITEMS OF INTEREST

In order to meet the demand for improved communication and better cooperation between the American Board of Psychiatry and Neurology and its constituent organizations, the Board will be issuing summaries of Neurology to *Psychiatric News* and other relevant publications from time to time. The Board welcomes comments and suggestions on all the items reported.

Members of the American Board of Psychiatry and Neurology met with Trustees and council chairmen of the APA for several hours on December 6, 1975, during the meetings of the Board of Trustees. A vigorous interchange ensued and much clarification was achieved. In particular it was pointed out that the ABPN members are *elected* by that Board from *nominations* submitted by parent organizations: the American Psychiatric Association, the American Medical Association, the American Neurological Association, and the American Academy of Neurology. Misunderstanding has arisen in the past from the assumption that the ABPN members were *elected* by parent bodies. Qualifications for Board membership and procedures for nominations are now being formulated by the APA Council on Medical Education and Career Development, with consultation by ABPN.

American Board of Psychiatry and Neurology members met with the full session of the American Association of Directors of Psychiatric Residency Training Programs in New Orleans on January 17, 1976, prior to the examination being held in that city. Dr. Milton Greenblatt, President of the Board, discussed a series of questions that had been submitted to him in advance, followed by lively discussions from the floor. Meetings were also scheduled with the American Association of Chairmen of Departments of Psychiatry in Miami, and two panels on residency training were scheduled for the convention to which members of the Board will contribute.

In its policy meetings in New Orleans, January 17–18, 1976, the American Board of Psychiatry and Neurology took the following significant actions:

1. Agreed to develop a contract with the Audio-Visual Education Service at the Veterans Administration Hospital, Brentwood, Calif., for further exploration of audiovisual techniques.
2. Authorized the development of a design for a validation study to determine the relationship between performance on the examination and clinical competence in the field. Organized a cohort study of 100 psychiatrist and 100 neurologist candidates to identify their performance over time.
3. Raised the fees for examinations as follows: Application fee increased by $10, to $135; Part I (written) examination fee raised by $50, to $100; and Part II (oral) examination

fee raised by $40, to $190. It was noted that examination fees had not been raised by the Board for three years and that both inflation and increased expenses made this decision necessary.

4. Received a report from the Child Psychiatry Committee (Dr. John McDermott, chairperson) indicating progress in technical improvement of the child psychiatry examination and updating developments from their evaluation study.

5. Agreed to collaborate with the American Association of Directors of Psychiatric Residency Training Programs in preparing a questionnaire on the postgraduate year and to share in the expenses.

6. Referred to the Examination Committee for implementation a request by the APA Committee on Ethics that questions on ethics be incorporated into the American Board of Psychiatry and Neurology examination.

7. Appointed a search committee to recruit a full-time executive officer for the American Board of Psychiatry and Neurology with qualifications as an administrator and educator, and, especially, with ability to develop research in educational and examination procedures.

In its policy meeting in Los Angeles, April 10–11, the American Board of Psychiatry and Neurology took the following significant actions:

1. Approved elimination of the two-year experience requirement for admission to the Part II (oral) examination.

2. Approved an expanded and more detailed guideline for examiners in evaluating performance of candidates in the oral examination.

3. Approved plans to make the audiovisual examination operative for the October 1976 oral examination in Chicago. The audiovisual examination will replace one of the clinical hours in psychiatry and one of the clinical hours in neurology.

4. Instructed the central office to set up a mechanism for feedback of examination results to program directors as follows: for those candidates giving permission, examination results will be conveyed to their program directors; results for a series of candidates trained in a given program will be analyzed and the generalizations as to their collective performance will be conveyed to the training program director without divulging the identity of any given candidate.

5. Appointed a committee to delineate more specifically the areas of required knowledge in the written examination, with illustrations of the types of questions normally asked in this examination.

6. Received a report on the Child Psychiatry Examination of 106 candidates examined in Los Angeles, March 8–9, and discussed in detail the results of a very successful post-examination conference on "Roles and Functions of the Child Psychiatrist" held April 4–7 in Silverado, Calif. (Dr. John McDermott reporting).

7. Reviewed progress on two research projects: relevance of Board Examination to clinical competence, and study of examination results for cohorts in psychiatry and neurology.

LESTER H. RUDY, M.D.
Executive Director

EDITOR'S NOTE: In accordance with an action of the Board of Trustees at its June 1976 meeting, all documents pertaining to the Constitution and By-Laws, including the Report of the Committee on Constitution and By-Laws, will be published in the December 17, 1976, issue of *Psychiatric News*.

Results of 11 controlled studies[1] evaluated by the Brief Psychiatric Rating Scale to determine the efficacy of LOXITANE® Loxapine Succinate by comparing it with trifluoperazine and chlorpromazine. They do not imply a claim of differential effectiveness or superiority. However, certain trends, not statistically significant, suggest superiority. These require further tests for confirmation.

Loxitane®
LOXAPINE SUCCINATE
Lederle

From the record:

LOXITANE has favorable trends

In 31 dose-range, long-term and controlled efficacy studies involving 469 acute and chronic schizophrenic patients...

Certain favorable trends were exhibited in the LOXITANE side effects profile; these require further tests and broader clinical experience for confirmation.

exhibited certain in side effects profile

While cardiac arrest, blood dyscrasias and renal toxicity have been reported with other antipsychotic agents, they have not been seen with LOXITANE. Hepatotoxicity manifested by jaundice or biliary stasis has not been observed. Transient liver enzyme changes, however, have been reported, but it has not been determined whether they are related to LOXITANE administration.

Although a few cases of changes in ECG have been reported, a causal relationship between this reaction and LOXITANE has not been established. Clinical experience with LOXITANE has not demonstrated ocular toxicity, however, the possibility of its occurrence cannot be ruled out at this time. Of the various endocrine abnormalities, only galactorrhea has been noted with LOXITANE, and only in rare instances.

Manifestations of adverse effects on the central nervous system other than extrapyramidal symptoms have been encountered infrequently, and drowsiness, when it occurs, is usually mild and subsides with continued therapy. Skin rashes of uncertain etiology have been observed in a few patients during the hot summer months; therefore the possibility of phototoxicity and/or photosensitivity cannot be excluded. Like certain other antipsychotic agents, LOXITANE lowers the convulsive threshold and should be used with extreme caution in patients with a history of convulsive disorders.

In general, LOXITANE presents a profile of extrapyramidal side effects similar to that of other agents used in the treatment of schizophrenia.

Cardiovascular effects such as hypotension, hypertension, light-headedness and syncope have been reported. Anticholinergic effects seen with LOXITANE include dry mouth, nasal congestion, constipation and blurred vision.

See LOXITANE prescribing information on next page for contraindications, warnings and precautions and for more detailed information concerning side effects.

A range of dosage strengths to suit the patient's individual needs

Supplied

Capsules

10 mg Green and Yellow

25 mg Green Two Tone

50 mg Green and Blue

Recommended Daily Dosage

Initial Dosage	MILD 10 mg b.i.d.	MODERATE 10 mg t.i.d. or q.i.d.	SEVERE 25 mg b.i.d.
First 7 to 10 Days	Increase dosage until psychotic symptoms are controlled. Dosage should not exceed 250 mg/day. Usual dosage during titration: 50 to 150 mg/day.		
Maintenance Dosage	Adjust to lowest effective level. Usual maintenance dosage: 60 to 100 mg/day. Many patients are controlled with dosages as low as 20 to 60 mg/day.		

Loxitane®

LOXAPINE SUCCINATE

Lederle

Because efficacy and side effects are a single consideration

Loxitane®
LOXAPINE Lederle SUCCINATE

Because efficacy and side effects are a single consideration

FOR ORAL USE

DESCRIPTION

LOXITANE *loxapine*, a dibenzoxazepine compound, represents a new subclass of tricyclic antipsychotic agent, chemically distinct from the thioxanthenes, butyrophenones, and phenothiazines. Chemically, it is 2-chloro-11-(4-methyl-1-piperazinyl)dibenz[b,f] [1,4]oxazepine. It is present in capsules as the succinate salt. Each 1.36 mg. of loxapine succinate is equivalent to 1 mg. of loxapine.

ACTIONS

Pharmacologically, loxapine is a tranquilizer for which the exact mode of action has not been established. However, changes in the level of excitability of subcortical inhibitory areas have been observed in several animal species in association with such manifestations of tranquilization as calming effects and suppression of aggressive behavior.

In normal human volunteers, signs of sedation were seen within 20 to 30 minutes after administration, were most pronounced within 1½ to 3 hours, and lasted through 12 hours. Similar timing of primary pharmacologic effects was seen in animals.

Absorption of loxapine following oral or parenteral administration is virtually complete. The drug is removed rapidly from the plasma and distributed in tissues. Animal studies suggest an initial preferential distribution in lungs, brain, spleen, heart, and kidney. Loxapine is metabolized extensively and is excreted mainly in the first 24 hours. Metabolites are excreted in the urine in the form of conjugates and in the feces unconjugated.

INDICATIONS

LOXITANE *loxapine succinate* is indicated for the manifestations of schizophrenia.

LOXITANE has not been evaluated for the management of behavioral complications in patients with mental retardation, and therefore it cannot be recommended.

CONTRAINDICATIONS

LOXITANE is contraindicated in comatose or severe drug-induced depressed states (alcohol, barbiturates, narcotics, etc.)

LOXITANE is contraindicated in individuals with known hypersensitivity to the drug.

WARNINGS

Usage in Pregnancy—Safe use of LOXITANE *loxapine succinate* during pregnancy or lactation has not been established; therefore, its use in pregnancy, in nursing mothers, or in women of childbearing potential requires that the benefits of treatment be weighed against the possible risks to mother and child. No embryotoxicity or teratology was observed in studies in rats, rabbits or dogs, although with the exception of one rabbit study, the highest dosage was only two times the maximum recommended human dose and in some studies they were below this dose. Perinatal studies have shown renal papillary abnormalities in offspring of rats treated from mid-pregnancy with doses of 0.6 and 1.8 mg/kg, doses which approximate the usual human dose but which are considerably below the maximum recommended human dose.

Usage in Children—Studies have not been performed in children; therefore this drug is not recommended for use in children below the age of 16.

LOXITANE, like other tranquilizers, may impair mental and/or physical abilities, especially during the first few days of therapy. Therefore, ambulatory patients should be warned about activities requiring alertness (eg, operating vehicles or machinery), and about concomitant use of alcohol and other CNS depressants.

PRECAUTIONS

LOXITANE should be used with extreme caution in patients with a history of convulsive disorders since it lowers the convulsive threshold. Seizures have been reported in epileptic patients receiving LOXITANE at antipsychotic dose levels, and may occur even with maintenance of routine anticonvulsant drug therapy.

Loxapine has an antiemetic effect in animals. Since this effect may also occur in man, loxapine may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

LOXITANE should be used with caution in patients with cardiovascular disease. Increased pulse rates have been reported in the majority of patients receiving antipsychotic doses; transient hypotension has been reported. In the presence of severe hypotension requiring vasopressor therapy, the preferred drugs may be norepinephrine or angiotensin. Usual doses of epinephrine may be ineffective because of inhibition of its vasopressor effect by loxapine.

The possibility of ocular toxicity from loxapine cannot be excluded at this time. Therefore, careful observation should be made for pigmentary retinopathy and lenticular pigmentation since these have been observed in some patients receiving certain other antipsychotic drugs for prolonged periods.

Because of possible anticholinergic action, the drug should be used cautiously in patients with glaucoma or a tendency to urinary retention, particularly with concomitant administration of anticholinergic-type antiparkinson medication.

ADVERSE REACTIONS

CNS Effects—Manifestations of adverse effects on the central nervous system, other than extrapyramidal effects, have been seen infrequently. Drowsiness, usually mild, may occur at the beginning of therapy or when dosage is increased.

It usually subsides with continued LOXITANE therapy. The incidence of sedation has been less than that of certain aliphatic phenothiazines and slightly more than the piperazine phenothiazines. Dizziness, faintness, staggering gait, muscle twitching, weakness, and confusional states have been reported.

Extrapyramidal Reactions—Neuromuscular (extrapyramidal) reactions during the administration of LOXITANE *loxapine succinate* have been reported frequently, often during the first few days of treatment. In most patients, these reactions involved Parkinson-like symptoms such as tremor, rigidity, excessive salivation, and masked facies. Akathisia (motor restlessness) also has been reported relatively frequently. These symptoms are usually not severe and can be controlled by reduction of LOXITANE dosage or by administration of antiparkinson drugs in usual dosage. Dystonic and dyskinetic reactions have occurred less frequently, but may be more severe. Dystonias include spasms of muscles of the neck and face, tongue protrusion, and oculogyric movement. Dyskinetic reaction has been described in the form of choreo-athetoid movements. These reactions sometimes require reduction or temporary withdrawal of LOXITANE dosage in addition to appropriate counteractive drugs.

Persistent Tardive Dyskinesia—As with all antipsychotic agents, tardive dyskinesia may appear in some patients on long-term therapy or may appear after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movement of the tongue, face, mouth, or jaw (eg, protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia; antiparkinson agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been suggested that fine vermicular movements of the tongue may be an early sign of the syndrome, and if the medication is stopped at that time the syndrome may not develop.

Cardiovascular Effects—Tachycardia, hypotension, hypertension, lightheadedness, and syncope have been reported.

A few cases of ECG changes similar to those seen with phenothiazines have been reported. It is not known whether these were related to loxapine administration.

Skin—Dermatitis, edema (puffiness of face), pruritus, and seborrhea have been reported with loxapine. The possibility of photosensitivity and/or phototoxicity occurring has not been excluded; skin rashes of uncertain etiology have been observed in a few patients during hot summer months.

Anticholinergic Effects—Dry mouth, nasal congestion, constipation, and blurred vision have occurred; these are more likely to occur with concomitant use of antiparkinson agents.

Other Adverse Reactions—Nausea, vomiting, weight gain, weight loss, dyspnea, ptosis, hyperpyrexia, flushed facies, headache, paresthesia, and polydipsia have been reported in some patients. Rarely, galactorrhea and menstrual irregularity of uncertain etiology have been reported.

DOSAGE AND ADMINISTRATION

LOXITANE *loxapine succinate* is administered orally usually in divided doses two to four times a day. Daily dosage (in terms of base equivalents) should be adjusted to the individual patient's needs as assessed by the severity of symptoms and previous history of response to antipsychotic drugs. Initial dosage of 10 mg twice daily is recommended, although in severely disturbed patients initial dosage up to a total of 50 mg daily may be desirable. Dosage should then be increased fairly rapidly over the first seven to ten days until there is effective control of psychotic symptoms. The usual therapeutic and maintenance range is 60 mg to 100 mg daily. However, as with other antipsychotic drugs, some patients respond to lower dosage and others require higher dosage for optimal benefit. Daily dosage higher than 250 mg is not recommended. For maintenance therapy, dosage should be reduced to the lowest level compatible with symptom control; many patients have been maintained satisfactorily at dosages in the range of 20 mg to 60 mg daily.

HOW SUPPLIED

LOXITANE *loxapine succinate* is supplied in the following base equivalent strengths:

CAPSULES Hard Shell Printed "Lederle"

10 mg—Green and Yellow; Bottles of 100, 1000, and unit dose 10 x 10's—Product Number 5360.

25 mg—Green Two Tone; Bottles of 100, 1000, and unit dose 10 x 10's—Product Number 5361.

50 mg—Green and Blue; Bottles of 100, 1000, and unit dose 10 x 10's—Product Number 5362.

The B24 III

UL LISTED

...a new generation of electroconvulsive therapy instrumentation from Medcraft.

Designed with patient and operator safety in mind, this new series of instrumentation meets the rigorous requirements for listing by Underwriters Laboratories — UL 544, Standards for Medical and Dental Equipment. The B24 III provides the physician with the ultimate in precision dosage levels. Consistancy of desired output level is assured with the following features:

- Line Voltage Compensation -- allows compensation for fluctuations in incoming line voltages.
- Pre-programmed Voltage Selection — choice of eleven voltage levels from 70 volts to 170 volts.
- Automatic Treatment Timing — adjustable from 0.1 second to 1.0 second with or without Glissando.
- Current Output Indicators — visual assurance of current flow during treatment.

Exclusive Patient Test Module allows a complete systems integrity check of instrumentation prior to treatment. Clinical accuracy and dependability are assured by the use of 100% solid state circuitry. Double shielded transformer provides an additional margin of treatment safety. For ordering information, specifications and prices, write or call directly to:

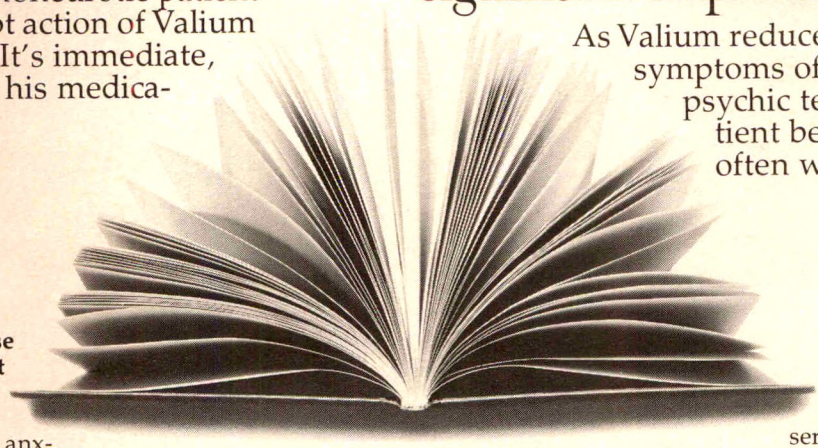
Valium®
(diazepam) IV
2-mg, 5-mg, 10-mg scored tablets
Please turn page for summary of product information

Patient response you can depend on.

Valium® (diazepam)



2-mg, 5-mg, 10-mg scored tablets

Initial calming in hours.

Your anxious psychoneurotic patient will find the prompt action of Valium highly reassuring. It's immediate, tangible proof that his medication is working.

Significant improvement in days.

As Valium reduces overwhelming symptoms of anxiety and psychic tension, your patient begins to feel better often within a few days.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states; somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence. In pregnancy, lactation or women of childbearing age, weigh potential benefit against possible hazard.

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10.

For the patient who needs a UNIQUE CONCEPT in MEDICAL and HOSPITAL CARE.

Las Encinas Hospital

Under complete supervision and direction of its Medical Staff, Las Encinas Hospital offers evaluation and treatment of a patient's total individual needs . . . psychological and physical.

A full time staff of Board certified specialists in Psychiatry, Internal Medicine, Radiology and Psychology, backed by a fully equipped and accredited hospital facility, offers clinical study, diagnosis, and long or short term care. All in a decidedly unhospital-like atmosphere of restful beauty, comfort, privacy and security. Rooms, suites and cottage accommodations available.

Write for our Illustrated Booklet:

Stephen Smith III, M.D. • *Medical Director*

Robert D. Tonry • *Hospital Administrator*

FOUNDED IN 1904

Fully Accredited by the JCAH, Approved by A.P.A., Member of All Major Hospital Associations.

2900 E. Del Mar Blvd. • Pasadena, CA 91107

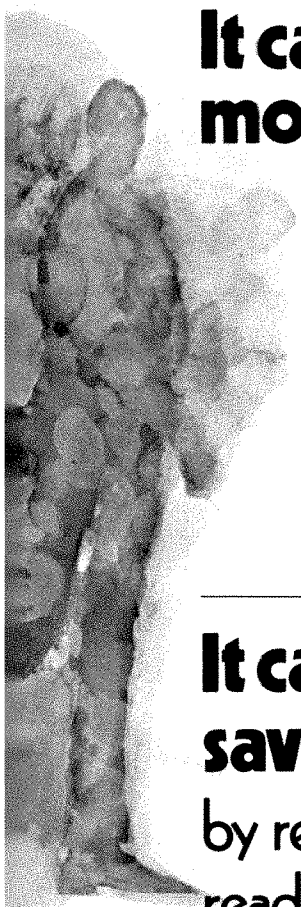
Wi[illegible] t[illegible] lon[illegible]-ting injectable phenothiazine do that a short-acting oral can't?



It can save time

Prolixin Decanoate (Fluphenazine Decanoate Injection), with duration of action that may last up to 4 weeks or longer in patients on maintenance therapy, can effect important savings in nursing time.

Approximate Staff Time Required to Medicate 18 Schizophrenic Patients*

	
8 a.m. ¾ hr. 1 p.m. ¾ hr. 6 p.m. ¾ hr.	1 injection every 28 days for most patients
= 2¼ hours nursing time	4 minutes required for each injection
2¼ hrs. x 28 days = 63 hours of nursing time every 28 days	= 1 hr., 10 minutes nursing time in 28 days
NURSING TIME SAVED IN 28 DAYS	61 hours and 50 minutes or more than 7½ eight-hour working days

*Adapted from Platt R. Br J Social Psychiatry 2: 187-191, 1968.

It can save money

Martin and Townend[1], who found from their study of Prolixin Decanoate that 15 of 39 patients could be maintained on 25 mg. every 4 weeks, also note that on this basis "a year's maintenance on chlorpromazine represents the order of 110 grams of phenothiazine as opposed to 0.33 gram of fluphenazine." Translating this into dollars shows the following potential hospital savings on the basis of patient population:

Agent and amount/year	Form	Cost/patient/ year	Cost/500 patients/ year
Chlorpromazine (SKF brand) 110 grams	8 oz. concentrate 100 mg./ml.†	$48.75*	$24,375
Prolixin Decanoate .33 grams	5 ml. vials 25 mg./ml.	$26.08**	$13,040
SAVINGS		$22.67 patient, year	$11,335 500 pts/yr.

* Calculated from prices published in 1976 Red Book.
** Calculated from Squibb 1976 price catalogue.
† With tablets, the annual cost is even greater.

It can even save people– by reducing readmissions

The controlled drug delivery system of Prolixin Decanoate helps get schizophrenic patients out of the hospital and helps them stay out. It promotes continuity of therapy—reducing outpatient drug defaulting from approximately 50% with oral medications according to one report[2] to about 16% according to another report[3].

It reduces the number and length of rehospitalizations. In one study of 103 patients maintained on injections of long-acting fluphenazines, total hospital readmissions for a year were cut from 191 to 50 and inpatient time from 8,713 days to 1,335 days[4].

It facilitates return to a productive life. A 12-month followup of 103 discharged patients revealed 77% in full-time employment or household duties and only 23% unemployed[4].

SQUIBB

Prolixin Decanoate®

Fluphenazine Decanoate Injection

may control schizophrenic symptoms for up to 4 weeks or longer in patients on maintenance therapy.

See next page for brief summary of prescribing information.

Prolixin Decanoate®

Fluphenazine Decanoate Injection

may control schizophrenic symptoms for up to 4 weeks or longer in patients on maintenance therapy.

Prolixin Decanoate (Fluphenazine Decanoate Injection) provides 25 mg. fluphenazine decanoate per ml. in a sesame oil vehicle with 1.2% (w/v) benzyl alcohol as a preservative.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain damage. In patients who have a blood dyscrasia or liver damage, or who are receiving large doses of hypnotics, or who are comatose or severely depressed. In patients who have shown hypersensitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

Not intended for use in children under 12.

WARNINGS: Mental and physical abilities required for driving a car or operating heavy machinery may be impaired by use of this drug. Physicians should be alert to the possibility that severe adverse reactions may occur which require immediate medical attention. Potentiation of effects of alcohol may occur. Safety and efficacy in children have not been established because of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; weigh possible hazards against potential benefits if administering this drug to pregnant patients.

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused cholestatic jaundice, dermatoses or other allergic reactions because of the possibility of cross-sensitivity. When psychotic patients on large doses of a phenothiazine drug are to undergo surgery, hypotensive phenomena should be watched for; less anesthetics or central nervous system depressants may be required. Because of added anticholinergic effects, fluphenazine may potentiate the effects of atropine.

Use fluphenazine decanoate cautiously in patients exposed to extreme heat or phosphorus insecticides; in patients with a history of convulsive disorders since grand mal convulsions have occurred; and in patients with special medical disorders such as mitral insufficiency or other cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged therapy there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal deposits, and development of irreversible dyskinesia.

Fluphenazine decanoate should be administered under the direction of a physician experienced in the clinical use of psychotropic drugs. Periodic checking of hepatic and renal functions and blood picture should be done. Renal function of patients on long-term therapy should be monitored; if BUN becomes abnormal, treatment should be discontinued. "Silent pneumonias" are possible.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are most frequently reported. These include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthotonos, and hyperreflexia; most often these are reversible, but they may be persistent. One can expect a higher incidence of such reactions with fluphenazine decanoate than with less potent piperazine derivatives or straight-chain phenothiazines. The incidence and severity will depend more on individual patient sensitivity, but dosage level and patient age are also determinants. As these reactions may be alarming, the patient should be forewarned and reassured. These reactions can usually be controlled by administration of antiparkinsonian drugs such as benztropine mesylate or intravenous Caffeine and Sodium Benzoate Injection U.S.P., and by subsequent reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and sometimes irreversible tardive dyskinesia may appear in some patients on long-term therapy or may occur after discontinuation of drug. The risk seems greater in elderly patients, especially females, on high dosages. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and may be accompanied by involuntary movements of extremities. There is no known effective therapy for tardive dyskinesia; usually the symptoms are not alleviated by antiparkinsonism agents. If the symptoms appear, discontinuation of all antipsychotic agents is suggested. The syndrome may be masked if treatment is reinstituted, or drug dosage increased, or a different antipsychotic agent used. Reports are that fine vermicular movements of the tongue may be an early sign of the syndrome which may not develop if medication is stopped at that time.

Phenothiazine derivatives have been known to cause restlessness, excitement, or bizarre dreams; reactivation or aggravation of psychotic processes may be encountered. If drowsiness or lethargy occur, the dosage may have to be reduced. Dosages, far in excess of the recommended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure have been reported. Although hypotension is rarely a problem, patients with pheochromocytoma, cerebral vascular or renal insufficiency or severe cardiac reserve deficiency such as mitral insufficiency appear to be particularly prone to this reaction and should be observed carefully. Supportive measures including intravenous vasopressor drugs should be instituted immediately should severe hypotension occur; Levarterenol Bitartrate Injection U.S.P. is the most suitable drug; *epinephrine should not be used* since phenothiazine derivatives have been found to reverse its action. Nausea, loss of appetite, salivation, polyuria, perspiration, dry mouth, headache and constipation may occur. Reducing or temporarily discontinuing the dosage will usually control these effects. Blurred vision, glaucoma, bladder paralysis, fecal impaction, paralytic ileus, tachycardia, or nasal congestion have occurred in some patients on phenothiazine derivatives.

Metabolic and Endocrine—Weight change, peripheral edema, abnormal lactation, gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in men and increased libido in women have occurred in some patients on phenothiazine therapy.

Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, eczema and exfoliative dermatitis have been reported with phenothiazines. The possibility of anaphylactoid reactions should be borne in mind.

Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocytopenic or nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been observed with phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper respiratory infection occur and confirmatory leukocyte count indicates cellular depression, therapy should be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during the first months of therapy, may occur; treatment should be discontinued. A cephalin flocculation increase, sometimes accompanied by alterations in other liver function tests, has been reported in patients who have had no clinical evidence of liver damage.

Others—Sudden deaths have been reported in hospitalized patients on phenothiazines. Previous brain damage or seizures may be predisposing factors. High doses should be avoided in known seizure patients. Shortly before death, several patients showed flare-ups of psychotic behavior patterns. Autopsy findings have usually revealed acute fulminating pneumonia or pneumonitis, aspiration of gastric contents, or intramyocardial lesions. Although not a general feature of fluphenazine, potentiation of central nervous system depressants such as opiates, analgesics, antihistamines, barbiturates and alcohol may occur.

Systemic lupus erythematosus-like syndrome, hypotension severe enough to cause fatal cardiac arrest, altered electrocardiographic and electroencephalographic tracings, altered cerebrospinal fluid proteins, cerebral edema, asthma, laryngeal edema, and angioneurotic edema; with long-term use, skin pigmentation and lenticular and corneal opacities have occurred with phenothiazines. Local tissue reactions occur only rarely with injections of fluphenazine decanoate.

For full prescribing information, consult package insert.

HOW SUPPLIED: 1 ml. Unimatic® single dose preassembled syringes and cartridge-needle units, and 5 ml. vials.

The Rape Victim

by Elaine Hilberman, M.D.

Mythologies about rape are legion. However, in recent years behavioral scientists have accumulated a body of information about rape and about an unfolding series of reactions experienced by the victim after rape. The aim of this concise, tightly reasoned book is to summarize what is now known about the needs and experiences of the victim and her family, and to provide a framework in which the clinician can more knowledgeably supply assistance and support. This document, published by the American Psychiatric Association, is the result of a project of the Association's Committee on Women.

Pointing out that the profound impact of rape stress is best understood in the context of rape as "a crime against the person and not the hymen," Dr. Hilberman sees rape as the ultimate violation of the self short of homicide, as an act of violence and humiliation in which not only is the victim's very existence threatened, and her inner and most private space invaded, but her autonomy and control are totally demolished. Dr. Hilberman shows that if and when the victim reports the crime, she is confronted with a complex series of yet additional stresses growing out of her contact with the hospital, police, courts, media and community opinion. Additionally, her crisis differs from other crises in that her usual social support system is likely to be disrupted. Her immediate needs are for empathy and safety, and a sense of control over what is happening in her dealings with the several agencies. Dr. Hilberman shows that in the absence of sensitivity to these needs, the experience of reporting becomes another assault.

This book presents a professional, sobering, and balanced picture of the problems of the rape victim and details what the clinician must know—about local hospital policy, criminal justice procedure, rape statutes, and community attitudes and services—in order to be able to treat victims with an understanding of the larger context in which rape occurs.

MENTAL
HEALTH
CLINIC

Haldol®
(haloperidol)
tablets/concentrate/injection

For long-term control with minimal risk of toxicity

Highly effective in a wide range of psychotic symptoms,[1-7] such as hallucinations, delusions, suspiciousness, hostility, mania, psychomotor agitation, etc., in both acute and chronic disorders.

Usually leaves patients relatively alert and responsive...[1-3] better able to cope with job and family responsibilities...as well as easier to reach with supportive and rehabilitative measures.

Permits aggressive titration to effective dosage levels,[1,4] up to 100 mg/day orally (with minimal risk of usual troublesome reactions) to achieve optimal response when patient is inadequately controlled at lower dosage...to help you rapidly control and stabilize new patients, promptly regain control during periods of exacerbation.

Common side effects easily controlled.[1,3-6] Although extrapyramidal symptoms (EPS) have been reported frequently, they are usually dose-related and readily controlled with dose adjustment or antiparkinson drugs. EPS often diminish spontaneously with continued use of HALDOL haloperidol.

*Not an actual case history, this situation illustrates the action of HALDOL haloperidol as reported in various clinical studies (available on request).

Reduces risk of certain troublesome reactions.[2-5,7] Transient hypotension occurs rarely and severe orthostatic hypotension has not been reported. Marked sedation is rare, although some instances of drowsiness have been reported. In addition, with chronic use, it is unlikely to cause hepatic damage, serious hematologic reactions, photosensitivity reactions and skin rashes...and has minimal effect on renal function.

Please turn page for information relating to Indications, Contraindications, Warnings, Precautions and Adverse Reactions.

Important: Full directions for use should be read before HALDOL haloperidol is administered or prescribed.

Haldol® (haloperidol)

tablets/concentrate/injection

For long-term control of psychotic symptoms with minimal risk of toxicity

A Dosage Form for Every Need:

5 tablet strengths for convenience in individualizing dosage: ½ mg., 1 mg., 2 mg., 5 mg. and 10 mg.

A tasteless, odorless, colorless liquid concentrate for better patient acceptability: 2 mg. per ml.

A rapid-acting injection for psychiatric emergencies: 5 mg. per ml., with 1.8 mg. methylparaben and 0.2 mg. propylparaben per ml., and lactic acid for pH adjustment to 3.4±0.2.

Indications: HALDOL haloperidol is indicated for use in the management of manifestations of psychotic disorders.

It is also indicated for the control of tics and vocal utterances of Gilles de la Tourette's syndrome.

Contraindications: HALDOL haloperidol is contraindicated in patients who are severely depressed, comatose, have CNS depression due to alcohol or other centrally-acting depressants, have Parkinson's disease or are hypersensitive to this drug.

Warnings: ***Usage in Pregnancy:*** Safe use of HALDOL haloperidol in pregnancy and lactation has not been established; therefore, its use in pregnancy, in nursing mothers, or in women of childbearing potential requires that the possible benefits of the drug be weighed against the potential hazards. A case of phocomelia in an infant whose mother received haloperidol along with a number of other medications during the first trimester of pregnancy has been reported (a causal relationship was not established in this case). Animals receiving 2 to 20 times the maximum human dose of haloperidol orally and/or parenterally showed increased incidence of resorption, reduced fertility, delayed delivery, dose-related pup mortality (presumably due to lack of maternal care reflecting CNS depression).

Usage in Children: Safety and effectiveness in children have not been established; therefore, this drug is not recommended for use in the pediatric age group.

General: Cases of bronchopneumonia, some fatal, have followed the use of major tranquilizers, including haloperidol. It has been postulated that lethargy and decreased sensation of thirst may lead to dehydration, hemoconcentration and reduced pulmonary ventilation. If these signs and symptoms appear, especially in the elderly, the physician should institute remedial therapy promptly. Although not reported with HALDOL haloperidol, decreased serum cholesterol and/or cutaneous and ocular changes have been reported in patients receiving chemically-related drugs. HALDOL haloperidol may impair the mental and/or physical abilities required for the performance of hazardous tasks such as operating machinery or driving a motor vehicle. The ambulatory patient should be warned accordingly. The use of alcohol should be avoided due to possible additive effects and hypotension.

Precautions: HALDOL haloperidol should be administered cautiously to patients: (1)—with severe cardiovascular disorders, because of the possibility of transient hypotension and/or precipitation of anginal pain. Should hypotension occur and a vasopressor be required, epinephrine should not be used since HALDOL haloperidol may block its vasopressor activity and paradoxical further lowering of blood pressure may occur. (2)—receiving anticonvulsant medication, because HALDOL haloperidol may lower the convulsive threshold. Adequate anticonvulsant therapy should be maintained concomitantly. (3)—with known allergies, or with a history of allergic reactions to drugs. (4)—receiving anticoagulants, since an isolated instance of interference occurred with the effects of one anticoagulant (phenindione).

If concomitant antiparkinson medication is required, it may have to be continued after HALDOL haloperidol is discontinued because of the difference in excretion rates. If both are discontinued simultaneously, extrapyramidal symptoms may occur. Intraocular pressure may increase when anticholinergic drugs, including antiparkinson agents, are administered concomitantly with HALDOL haloperidol. When HALDOL haloperidol is used to control mania in cyclic disorders there may be a rapid mood swing to depression.

Adverse Reactions: ***CNS Effects:*** *Extrapyramidal Reactions*—Neuromuscular (extrapyramidal) reactions have been reported frequently, often during the first few days of treatment. Generally they involved Parkinson-like symptoms which usually were mild to moderately severe and reversible. Other types of neuromuscular reactions (motor restlessness, dystonia, akathisia, hyperreflexia, opisthotonos, oculogyric crises) have been reported far less frequently, but were often more severe. Severe extrapyramidal reactions have been reported at relatively low doses. Generally extrapyramidal symptoms are dose-related since they occur at relatively high doses and disappear or become less severe when the dose is reduced. Administration of antiparkinson drugs may be required for control of such reactions. Persistent extrapyramidal reactions have been reported and the drug may have to be discontinued in such cases. *Persistent Tardive Dyskinesia*—Tardive dyskinesia may appear during long-term therapy or after therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear irreversible. There is no known effective treatment. All antipsychotic agents should be discontinued. The syndrome may be masked by reinstitution of drug, increasing dosage, or switching to a different antipsychotic agent. *Other CNS Effects*—Insomnia, restlessness, anxiety, euphoria, agitation, drowsiness, depression, lethargy, headache, confusion, vertigo, grand mal seizures, and exacerbation of psychotic symptoms including hallucinations. ***Cardiovascular Effects:*** Tachycardia and hypotension. ***Hematologic Effects:*** Reports have appeared of mild and usually transient leukopenia and leukocytosis, minimal decreases in red blood cell counts, anemia, or a tendency toward lymphomonocytosis. Agranulocytosis has rarely been reported and then only in association with other medication. ***Liver Effects:*** Impaired liver function and/or jaundice have been reported, although a causal relationship has not been established. ***Dermatologic Reactions:*** Maculopapular and acneiform skin reactions and isolated cases of photosensitivity and loss of hair. ***Endocrine Disorders:*** Lactation, breast engorgement, mastalgia, menstrual irregularities, gynecomastia, impotence, increased libido, hyperglycemia and hypoglycemia. ***Gastrointestinal Effects:*** Anorexia, constipation, diarrhea, hypersalivation, dyspepsia, nausea and vomiting. ***Autonomic Reactions:*** Dry mouth, blurred vision, urinary retention and diaphoresis. ***Respiratory Effects:*** Laryngospasm, bronchospasm and increased depth of respiration.

Complete dosage information available in insert which accompanies each package (or on request).

The use of the injectable form is intended for the acutely agitated psychotic patient with moderately severe to very severe symptoms.

IMPORTANT: Full directions for use should be read before HALDOL haloperidol is administered or prescribed. 9-7

Coverage and Utilization of Care for Mental Conditions Under Health Insurance —Various Studies, 1973–74

By Louis S. Reed, Ph.D.
Consultant in Health Economics, American Psychiatric Association

This book reports six studies that add to the growing body of data demonstrating the feasibility of covering mental illness under health insurance. Although in some ways it may be considered a supplement to APA's 1972 book **HEALTH INSURANCE AND PSYCHIATRIC CARE: UTILIZATION AND COST** (Reed, Myers, and Scheidemandel), all of the data are new. The studies cover the following areas:

- Utilization of mental benefits under the Blue Cross and Blue Shield plan for federal employees, documenting that a "plateau" in the use of these benefits was reached in 1973–74.
- Comparison of benefits for mental and other illnesses under selected employee health benefit plans.
- Coverage of mental illness under collective bargaining agreements of selected unions.
- Utilization of care for mental conditions under the Canadian health insurance program, which gives the same coverage for mental as for other conditions.
- Updating of information on Blue Cross benefits for hospital care of mental illness.
- Data from selected Blue Cross and Blue Shield plans on coverage and utilization of mental conditions, with emphasis on major medical coverage.

80pp. Paperbound

Single copy, $4.00; 10–49 copies; $3.80 each; 50 or more copies, $3.20 each.

SPECIAL OFFER: One copy of this book (regular price, $4.00) and one copy of **HEALTH INSURANCE AND PSYCHIATRIC CARE: UTILIZATION AND COST** (regular price, $6.50) for $8.50.

In treating the schizophrenic, there's something different about

MOBAN®
(molindone HCl)

acts on the RAS with low incidence of adverse effects

EEG studies show that MOBAN® exerts its effect on the ascending reticular activating system. This often helps to encourage increased social participation, receptivity and communication in schizophrenic patients.

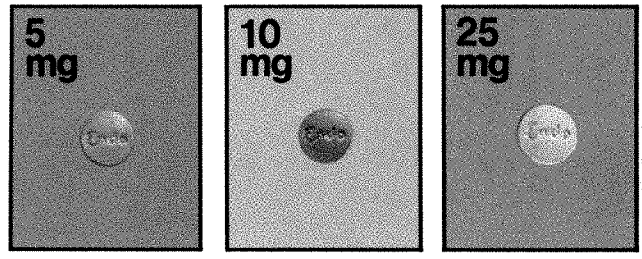
Artist's representation of the reticular activating system, with neuronal activity passing on to cortical and subcortical structures.

generally minimizes drowsiness to help produce improved functioning
1) to hasten the discharge of hospitalized patients
2) to keep ambulatory patients at home or on the job

tranquilizes without muscle relaxant or incoordinating effect

acts to alleviate target symptoms or reduce their severity
1) in acute patients, some symptomatic improvement evident in a few days
2) in chronic patients, symptomatic improvement may not be evident until 2-4 weeks
3) maximum benefits attained by end of third month (continued maintenance therapy as required)

SOCIAL ADJUSTMENT PROFILE CHART



of 66 hospitalized schizophrenic patients treated with MOBAN® (molindone HCl) for 1 year or more*

Adjustment	Percent
To live on open ward	91%
To function with privileges	89%
To hold hospital job	85%
To leave hospital	70%
To maintain home	33%
To hold employment	32%

*ata on file, Endo Laboratories

How to use MOBAN® (molindone HCl)

a wide range of dosage strengths available in **Tablets:**

- Titrate for 1) therapeutic response and 2) minimal effective maintenance dose.
- Use lower doses for the elderly and debilitated.

NOTE: Transient drowsiness may occur during the first 1-2 weeks.

Whenever your schizophrenic patient may benefit from less sedation

MOBAN
(molindone HCl)

Please see last page of advertisement for full prescribing information.

Moban® is an Endo registered U.S. trademark; U.S. Pat. 3,491,093.

DUPONT

MOBAN® (molindone HCl)

a dihydroindolone chemically distinct from phenothiazines, thioxanthenes, butyrophenones

DESCRIPTION MOBAN® (molindone hydrochloride) is a dihydroindolone compound which is not structurally related to the phenothiazines, the butyrophenones or the thioxanthenes.

MOBAN® is 3-ethyl-6, 7-dihydro-2-methyl-5-(morpholinomethyl) indol-4 (5H)-one hydrochloride. It is a white crystalline powder, freely soluble in water and alcohol and has a molecular weight of 312.67.

MOLINDONE HYDROCHLORIDE

ACTIONS MOBAN® (molindone hydrochloride) has a pharmacological profile in laboratory animals which predominantly resembles that of major tranquilizers causing reduction of spontaneous locomotion and aggressiveness, suppression of a conditional response and antagonism of the bizarre stereotyped behavior and hyperactivity induced by amphetamines. In addition, MOBAN® antagonizes the depression caused by the tranquilizing agent tetrabenazine.

In human clinical studies tranquilization is achieved in the absence of muscle relaxing or incoordinating effects. Based on EEG studies, MOBAN® exerts its effect on the ascending reticular activating system.

Human metabolic studies show MOBAN® (molindone hydrochloride) to be rapidly absorbed and metabolized when given orally. Unmetabolized drug reached a peak blood level at 1.5 hours. Pharmacological effect from a single oral dose persists for 24-36 hours. There are 36 recognized metabolites with less than 2-3% unmetabolized MOBAN® being excreted in urine and feces.

INDICATIONS MOBAN® (molindone hydrochloride) is indicated in the management of the manifestations of schizophrenia.

CONTRAINDICATIONS MOBAN® (molindone hydrochloride) is contraindicated in severe central nervous system depression (alcohol, barbiturates, narcotics, etc.) or comatose states, and in patients with known hypersensitivity to the drug.

WARNINGS Usage in Pregnancy: Studies in the pregnant patient have not been carried out. Reproduction studies have been performed in the following animals:

Pregnant Rats oral dose—	20 mg/kg/day—2 weeks
no adverse effect	
	40 mg/kg/day—2 weeks
no adverse effect	
Pregnant Mice oral dose—	20 mg/kg/day—9 days
slight increase resorptions	
	40 mg/kg/day—9 days
slight increase resorptions	
Pregnant Rabbits oral dose—	5 mg/kg/day—12 days
no adverse effect	
	10 mg/kg/day—12 days
no adverse effect	
	20 mg/kg/day—12 days
no adverse effect	

Animal reproductive studies have not demonstrated a teratogenic potential. The anticipated benefits must be weighed against the unknown risks to the fetus if used in pregnant patients.

Nursing Mothers: Data are not available on the content of MOBAN® (molindone hydrochloride) in the milk of nursing mothers.

Usage in Children: Use of MOBAN® (molindone hydrochloride) in children below the age of twelve years is not recommended because safe and effective conditions for its usage have not been established.

PRECAUTIONS Some patients receiving MOBAN® (molindone hydrochloride) may note drowsiness initially and they should be advised against activities requiring mental alertness until their response to the drug has been established.

Increased activity has been noted in patients receiving MOBAN®. Caution should be exercised where increased activity may be harmful.

MOBAN® does not lower the seizure threshold in experimental animals to the degree noted with more sedating antipsychotic drugs. However, convulsive seizures have been reported in a few instances.

The physician should be aware that this tablet preparation contains calcium sulfate as an excipient and that calcium ions may interfere with the absorption of preparations containing phenytoin sodium and tetracyclines.

MOBAN® has an antiemetic effect in animals. A similar effect may occur in humans and may obscure signs of intestinal obstruction or brain tumor.

ADVERSE REACTIONS CNS EFFECTS The most frequently occurring effect is initial drowsiness that generally subsides with continued usage of the drug or lowering of the dose.

Noted less frequently were depression, hyperactivity and euphoria.

Neurological

Extrapyramidal Reactions

Extrapyramidal reactions noted below may occur in susceptible individuals and are usually reversible with appropriate management.

Akathisia

Motor restlessness may occur early.

Parkinson Syndrome

Akinesia, characterized by rigidity, immobility and reduction of voluntary movements and tremor, have been observed. Occurrence is less frequent than akathisia.

Dystonic Syndrome

Prolonged abnormal contractions of muscle groups occur infrequently. These symptoms may be managed by the addition of a synthetic antiparkinson agent (other than L-dopa), small doses of sedative drugs, and/or reduction in dosage.

Autonomic Nervous System

Occasionally blurring of vision, tachycardia, nausea, dry mouth and salivation have been reported. Urinary retention and constipation may occur particularly if anticholinergic drugs are used to treat extrapyramidal symptoms.

Hematological

There have been rare reports of leucopenia and leucocytosis. If such reactions occur, treatment with MOBAN® may continue if clinical symptoms are absent. Alterations of blood glucose, liver function tests, B.U.N., and red blood cells have not been considered clinically significant.

Metabolic and Endocrine Effects

Alteration of thyroid function has not been significant. Amenorrhea has been reported infrequently. Resumption of menses in previously amenorrheic women has been reported. Initially heavy menses may occur. Lactation associated with MOBAN® therapy has not been reported. Increase in libido has been noted in some patients. Impotence has not been reported. Although both weight gain and weight loss have been in the direction of normal or ideal weight, excessive weight gain has not occurred with MOBAN®.

Cardiovascular

Rare, transient, non-specific T wave changes have been reported on E.K.G. Association with a clinical syndrome has not been established. Rarely has significant hypotension been reported.

Ophthalmological

Lens opacities and pigmentary retinopathy have not been reported where patients have received MOBAN® (molindone hydrochloride). In some patients, phenothiazine induced lenticular opacities have resolved following discontinuation of the phenothiazine while continuing therapy with MOBAN®.

Skin

Early, non-specific skin rash, probably of allergic origin, has occasionally been reported. Skin pigmentation has not been seen with MOBAN® usage alone.

MOBAN® (molindone hydrochloride) has certain pharmacological similarities to other antipsychotic agents. Because adverse reactions are often extensions of the pharmacological activity of a drug, all of the known pharmacological effects associated with other antipsychotic drugs should be kept in mind when MOBAN® is used. Upon abrupt withdrawal after prolonged high dosage an abstinence syndrome has not been noted.

Tardive Dyskinesia

Although not reported with MOBAN® (molindone hydrochloride) late appearing dyskinesias have been associated with certain antipsychotic agents.

Tardive dyskinesia associated with other agents has appeared in some patients on long-term therapy and has also appeared after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). There may be involuntary movements of extremities.

There is no known effective treatment of tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time the syndrome may not develop.

DOSAGE AND ADMINISTRATION Initial and maintenance doses of MOBAN® (molindone hydrochloride) should be individualized, and the minimal effective dose should be employed. Elderly and debilitated patients should be started on lower dosage.

DOSAGE SCHEDULE, BASED ON SEVERITY OF SYMPTOMATOLOGY

1. Mild—5 mg three or four times a day; an increase to 15 mg three or four times a day may be required.
2. Moderate—10 mg three or four times a day; an increase to 25 mg three or four times a day may be required.
3. Severe—daily dosage as high as 225 mg may be required.

DRUG INTERACTIONS Potentiation of drugs administered concurrently with MOBAN® (molindone hydrochloride) has not been reported. Additionally, animal studies have not shown increased toxicity when MOBAN® is given concurrently with representative members of three classes of drugs (i.e., barbiturates, chloral hydrate and antiparkinson drugs).

MANAGEMENT OF OVERDOSAGE Symptomatic, supportive therapy should be the rule.

Gastric lavage is indicated for the reduction of absorption of MOBAN® (molindone hydrochloride) which is freely soluble in water.

Since the adsorption of MOBAN® (molindone hydrochloride) by activated charcoal has not been determined, the use of this antidote must be considered of theoretical value.

Emesis in a comatose patient is contraindicated. Additionally, while the emetic effect of apomorphine is blocked by MOBAN® in animals, this blocking effect has not been determined in humans.

A significant increase in the rate of removal of unmetabolized MOBAN® from the body by forced diuresis, peritoneal or renal dialysis would not be expected. (Only 2% of a single ingested dose of MOBAN® is excreted unmetabolized in the urine.)

However, poor response of the patient may justify use of these procedures. While the use of laxatives or enemas might be based on general principles, the amount of unmetabolized MOBAN® in feces is less than 1%. Extrapyramidal symptoms have responded to the use of diphenhydramine (Benadryl*) and the synthetic anticholinergic antiparkinson agents (i.e., Artane*, Cogentin*, Akineton*).

HOW SUPPLIED As tablets in bottles of 100 and 1000 with potencies and colors as follows: 5 mg orange, 10 mg lavender, 25 mg light green.

*Benadryl—Trademark, Parke Davis and Co.
*Artane—Trademark, Lederle Laboratories
*Cogentin—Trademark, Merck Sharp & Dohme
*Akineton—Trademark, Knoll Pharmaceutical Co.

SINEQUAN®
DOXEPIN HCl

100-mg., 50-mg., 25-mg. Capsules and ORAL CONCENTRATE 10 mg./ml., 120-ml. (4-oz.) bottles

MAY BE AN APPROPRIATE CHOICE FOR YOUR NEXT PATIENT WITH CLINICAL DEPRESSION

See Brief Summary on last page of advertisement for information on adverse reactions, contraindications, warnings and precautions.

SINEQUAN®
DOXEPIN HCl

100-mg., 50-mg., 25-mg. Capsules and
ORAL CONCENTRATE 10 mg./ml., 120-ml. (4-oz.) bottles

Proved efficacy in the treatment of clinical depression

In the six years since its introduction, Sinequan (doxepin HCl) has objectively demonstrated its value in the treatment of clinical depression. Clinical studies have shown Sinequan to be unsurpassed in effectiveness when compared to other tricyclic antidepressants.

In addition, Sinequan may offer certain advantages not generally seen with some other drugs of its class:

Prompt sedative activity

Of the tricyclic antidepressants, Sinequan has been found to have one of the most prominent sedative effects.[1] This sedative property can be taken advantage of by administering the major portion of the daily dose *h.s.* Since clinically depressed patients frequently have accompanying sleep disturbances, this may be a valuable benefit.

Generally does not affect the activity of guanethidine at usual clinical doses[2]

"A new tricyclic antidepressant, doxepin, was evaluated for its ability to block the amine uptake mechanisms of the peripheral adrenergic neuron and blood platelet in man. At low doses, there was no evidence of inhibition of the amine pump." At clinical dosages up to 150 mg. per day, Sinequan can be given to man concomitantly with guanethidine and related compounds without blocking the antihypertensive effect.[2]

Cardiovascular effects, including hypotension and tachycardia, have been reported occasionally

In a series of double-blind comparative studies, 1,706 doxepin-treated patients were evaluated for side effects. Incidence of tachycardia was associated with only 45 (2.6%) clinically depressed/anxious patients. Incidence of symptomatic hypotension was associated with only 48 (2.8%) clinically depressed/anxious patients.[3]

SINEQUAN®
DOXEPIN HCl

100-mg., 50-mg., 25-mg. Capsules and
ORAL CONCENTRATE 10 mg./ml., 120-ml. (4-oz.) bottles

BRIEF SUMMARY
SINEQUAN® (doxepin HCl) Capsules/Oral Concentrate
Contraindications. Contraindicated in individuals who have shown hypersensitivity to the drug, and in patients with glaucoma or a tendency to urinary retention. Possibility of cross sensitivity with other dibenzoxepines should be kept in mind.
Warnings. The once-a-day dosage regimen of SINEQUAN in patients with intercurrent illness or patients taking other medications should be carefully adjusted. This is especially important in patients receiving other medications with anticholinergic effects.
Usage in Geriatrics: The use of SINEQUAN on a once-a-day dosage regimen in geriatric patients should be adjusted carefully based on the patient's condition.
Usage in Pregnancy: Reproduction studies performed in animals have shown no evidence of harm to the animal fetus. Since there is no experience in pregnant women receiving this drug, safety in pregnancy has not been established. There are no data with respect to the secretion of the drug in human milk and its effect on the nursing infant.
Usage in Children: Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.
MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug. The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered and the dosage involved.
Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug. Patients should also be cautioned that their response to alcohol may be potentiated.
Since suicide is an inherent risk in any depressed patient, and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy.
Should increased symptoms of psychosis or shift to manic symptomatology occur, it may be necessary to reduce dosage or add a major tranquilizer to the dosage regimen.
Adverse Reactions. NOTE: Some of the adverse reactions noted below have not been specifically reported with SINEQUAN use. However, due to the close pharmacological similarities among the tricyclics, the reactions should be considered when prescribing SINEQUAN.
Anticholinergic Effects: Dry mouth, blurred vision, constipation, and urinary retention have been reported. If they do not subside with continued therapy, or become severe, it may be necessary to reduce the dosage.
Central Nervous System Effects: Drowsiness is the most commonly noticed side effect. This tends to disappear as therapy is continued. Other infrequently reported CNS side effects are confusion, disorientation, hallucinations, numbness, paresthesias, ataxia, extrapyramidal symptoms and seizures.
Cardiovascular: Cardiovascular effects including hypotension and tachycardia have been reported occasionally.
Allergic: Skin rash, edema, photosensitization, and pruritus have occasionally occurred.
Hematologic: Eosinophilia has been reported in a few patients. There have been occasional reports of bone marrow depression manifesting as agranulocytosis, leukopenia, thrombocytopenia, and purpura.
Gastrointestinal: Nausea, vomiting, indigestion, taste disturbances, diarrhea, anorexia, and aphthous stomatitis have been reported. (See anticholinergic effects.)
Endocrine: Raised or lowered libido, testicular swelling, gynecomastia in males, enlargement of breasts and galactorrhea in the female, raising or lowering of blood sugar levels have been reported with tricyclic administration.
Other: Dizziness, tinnitus, weight gain, sweating, chills, fatigue, weakness, flushing, jaundice, alopecia, and headache have been occasionally observed as adverse effects.
Dosage and Administration. For most patients with illness of mild to moderate severity, a starting dose of 25 mg t.i.d. is recommended. Dosage may subsequently be increased or decreased at appropriate intervals and according to individual response. The usual optimum dose range is 75 mg/day to 150 mg/day.
In more severely ill patients an initial dose of 50 mg t.i.d. may be required with subsequent gradual increase to 300 mg/day if necessary. Additional therapeutic effect is rarely to be obtained by exceeding a dose of 300 mg/day.
In patients with very mild symptomatology or emotional symptoms accompanying organic disease, lower doses may suffice. Some of these patients have been controlled on doses as low as 25-50 mg/day.
As an alternative regimen, the total daily dosage, up to 150 mg, may be given on a once-a-day schedule without loss of effectiveness. This dose may be given at bedtime.
Anti-anxiety effect is apparent before the antidepressant effect. Optimal antidepressant effect may not be evident for two to three weeks.
Overdosage. A. Signs and Symptoms
1. Mild: Drowsiness, stupor, blurred vision, excessive dryness of mouth.
2. Severe: Respiratory depression, hypotension, coma, convulsions, cardiac arrhythmias and tachycardias.
Also: urinary retention (bladder atony), decreased gastrointestinal motility (paralytic ileus), hyperthermia (or hypothermia), hypertension, dilated pupils, hyperactive reflexes.
B. Management and Treatment
1. Mild: Observation and supportive therapy is all that is usually necessary.
2. Severe: Medical management of severe SINEQUAN overdosage consists of aggressive supportive therapy. If the patient is conscious, gastric lavage, with appropriate precautions to prevent pulmonary aspiration, should be performed even though SINEQUAN is rapidly absorbed. The use of activated charcoal has been recommended, as has been continuous gastric lavage with saline for 24 hours or more. An adequate airway should be established in comatose patients and assisted ventilation used if necessary. EKG monitoring may be required for several days, since relapse after apparent recovery has been reported. Arrhythmias should be treated with the appropriate antiarrhythmic agent. It has been reported that many of the cardiovascular and CNS symptoms of tricyclic antidepressant poisoning in adults may be reversed by the slow intravenous administration of 1 mg to 3 mg of physostigmine salicylate. Because physostigmine is rapidly metabolized, the dosage should be repeated as required. Convulsions may respond to standard anticonvulsant therapy; however, barbiturates may potentiate any respiratory depression. Dialysis and forced diuresis generally are not of value in the management of overdosage due to high tissue and protein binding of SINEQUAN.
Supply. Available as capsules containing doxepin HCl equivalent to 10 mg, 25 mg, 50 mg, and 100 mg doxepin in bottles of 100, 1000, and unit-dose packages of 100 (10 x 10's). SINEQUAN (doxepin HCl) 25 mg and 50 mg are also available in bottles of 5000. SINEQUAN Oral Concentrate is available in 120 ml bottles with an accompanying dropper calibrated at 5 mg, 10 mg, 15 mg, 20 mg, and 25 mg. Each ml contains doxepin HCl equivalent to 10 mg doxepin. Just prior to administration, SINEQUAN Oral Concentrate should be diluted with approximately 120 ml of water, whole or skimmed milk, or orange, grapefruit, tomato, prune or pineapple juice. SINEQUAN Oral Concentrate is not physically compatible with a number of carbonated beverages. For those patients requiring antidepressant therapy who are on methadone maintenance, SINEQUAN Oral Concentrate and methadone syrup can be mixed together with Gatorade®, lemonade, orange juice, sugar water, Tang®, or water; but not with grape juice. Preparation and storage of bulk dilutions is not recommended.
More detailed professional information available on request.

Pfizer **LABORATORIES DIVISION**
PFIZER INC.

In clinically significant depression

TABLETS, 5 mg and 10 mg

Vivactil®*

(Protriptyline HCl | MSD)

***When you want an antidepressant hat is characteristically nonsedating for he patient under close medical supervision Symptoms such as anxiety or agitation nay be aggravated.)**

r a brief summary of prescribing information please see following page.

MSD
MERCK SHARP & DOHME

In clinically significant depression

TABLETS, 5 mg and 10 mg

Vivactil®

(Protriptyline HCl|MSD)

Contraindications: Known hypersensitivity; acute recovery phase following myocardial infarction. Should not be given concomitantly with an MAOI; hyperpyretic crises, severe convulsions, and deaths have occurred in patients receiving tricyclic antidepressant and MAOI drugs simultaneously. When it is desired to substitute protriptyline HCl for an MAOI, a minimum of 14 days should be allowed to elapse after the latter is discontinued. Protriptyline HCl should then be initiated cautiously with gradual increase in dosage until optimum response is achieved.

Warnings: May block the antihypertensive effect of guanethidine or similarly acting compounds. May impair mental and/or physical abilities required for the performance of hazardous tasks, such as operating machinery or driving a motor vehicle. Should be used with caution in patients with a history of seizures and, because of its autonomic activity, in patients with a tendency to urinary retention or increased intraocular tension.

Tachycardia and postural hypotension may occur more frequently than with other antidepressant drugs. Should be used with caution in elderly patients and patients with cardiovascular disorders; such patients should be observed closely because of the tendency of the drug to produce tachycardia, hypotension, arrhythmias, and prolongation of the conduction time. Myocardial infarction and stroke have occurred with drugs of this class. On rare occasions, hyperthyroid patients or those receiving thyroid medication may develop arrhythmias when this drug is given.

Usage in Children: Not recommended for use in children because safety and effectiveness in the pediatric age group have not been established.

Usage in Pregnancy: Safe use in pregnancy and lactation has not been established; therefore, use in pregnant women, nursing mothers, or women who may become pregnant requires that possible benefits be weighed against possible hazards to mother and child.

Precautions: When protriptyline HCl is used to treat the depressive component of schizophrenia, psychotic symptoms may be aggravated; likewise, in manic-depressive psychosis, depressed patients may experience a shift toward the manic phase; paranoid delusions, with or without associated hostility, may be exaggerated. In any of these circumstances, it may be advisable to reduce the dose of protriptyline HCl or to use a major tranquilizing drug concurrently. Symptoms, such as anxiety or agitation, may be aggravated in overactive or agitated patients.

When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. May enhance response to alcohol and effects of barbiturates and other CNS depressants. Possibility of suicide in depressed patients remains during treatment and until significant remission occurs; this type of patient should not have access to large quantities of the drug. Concurrent administration with electroshock therapy may increase hazards of therapy; such treatment should be limited to patients for whom it is essential. Discontinue drug several days before elective surgery, if possible. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions which have not been reported with this specific drug. However, the pharmacologic similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when protriptyline HCl is administered. Protriptyline HCl is more likely to aggravate agitation and anxiety and produce cardiovascular reactions such as tachycardia and hypotension.

Cardiovascular: hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric: confusional states (especially in the elderly) with hallucinations, disorientation, delusions, anxiety, restlessness, agitation; insomnia, panic, and nightmares; hypomania; exacerbation of psychosis.

Neurological: numbness, tingling, and paresthesias of extremities; incoordination, ataxia, tremors, peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns, tinnitus.

Anticholinergic: dry mouth and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilatation of the urinary tract.

Allergic: skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight), edema (general, or of face and tongue), drug fever.

Hematologic: bone marrow depression; agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia.

Gastrointestinal: nausea and vomiting, anorexia, epigastric distress, diarrhea, peculiar taste, stomatitis, abdominal cramps, black tongue.

Endocrine: gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood sugar levels.

Other: jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency, nocturia; drowsiness, dizziness, weakness and fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache, and malaise.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of other tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.

How Supplied: Tablets, containing 5 mg and 10 mg protriptyline HCl each, in single-unit packages of 100 and bottles of 100 and 1000.

For more detailed information, consult your MSD representative or see full prescribing information.

MERCK SHARP & DOHME

Psychiatrist — Chairperson for School of Medicine Department of Psychiatry — State University of New York at Buffalo

Applicants must be graduates of an approved medical school and be certified by the American Board of Psychiatry. Must have established academic background, administrative ability and interest in teaching. Opportunity to develop a broadly-based clinically oriented Psychiatry Program with multi-institutional approach. Present Department has strong Ph.D. psychologist group and interfaces with an excellent University Psychology Department. Appointee would be expected to reorganize the Department with emphasis on recruitment of clinical faculty, residency program development, medical student instruction and interface with the Psychiatry Community. Send curriculum vitae to Dr. John R. Wright, Chairman of Search Committee for Chairperson of Department of Psychiatry. C/O Department of Pathology, 204 Farber Hall, State University of New York at Buffalo, Buffalo, New York 14214. The State University of New York at Buffalo is an equal opportunity affirmative action employer and welcomes applications from minorities and women.

POSITIONS AVAILABLE

Mental Health Facility Director

Unusual opportunity to function as Director of Modern Community based Mental Health Center in Bridgeport, Connecticut.

Board certified psychiatrists or those with a degree in Mental hospital administration or hospital administration certified by the A.P.A. are invited to apply. Salary $30,123 to $35,571.

Clinical Director (Forensic)

Responsible for the total medical/psychiatric care in a specialized treatment facility, centrally located in Middletown, Connecticut.

A unique opportunity is offered to a qualified, board certified applicant with Forensic training or experience. Salary $30,123 to $35,571.

Provisions exist for temporary state license. Two state medical schools provide for continuing professional growth and possibility for adjunctive faculty posts. A complete range of fringe benefits and many cultural and recreational opportunities are available. No restriction against modest non-conflicting private practice. Send vitae to:

James C. Johnson, M.D.
Deputy Commissioner
Department of Mental Health
90 Washington Street
Hartford, CT 06115

An Equal Opportunity M/F-Affirmative Action Employer.

Tested by time and experience in

1962

"...a considerable decrease of hyperactivity...."[1]
Knobel, 1962

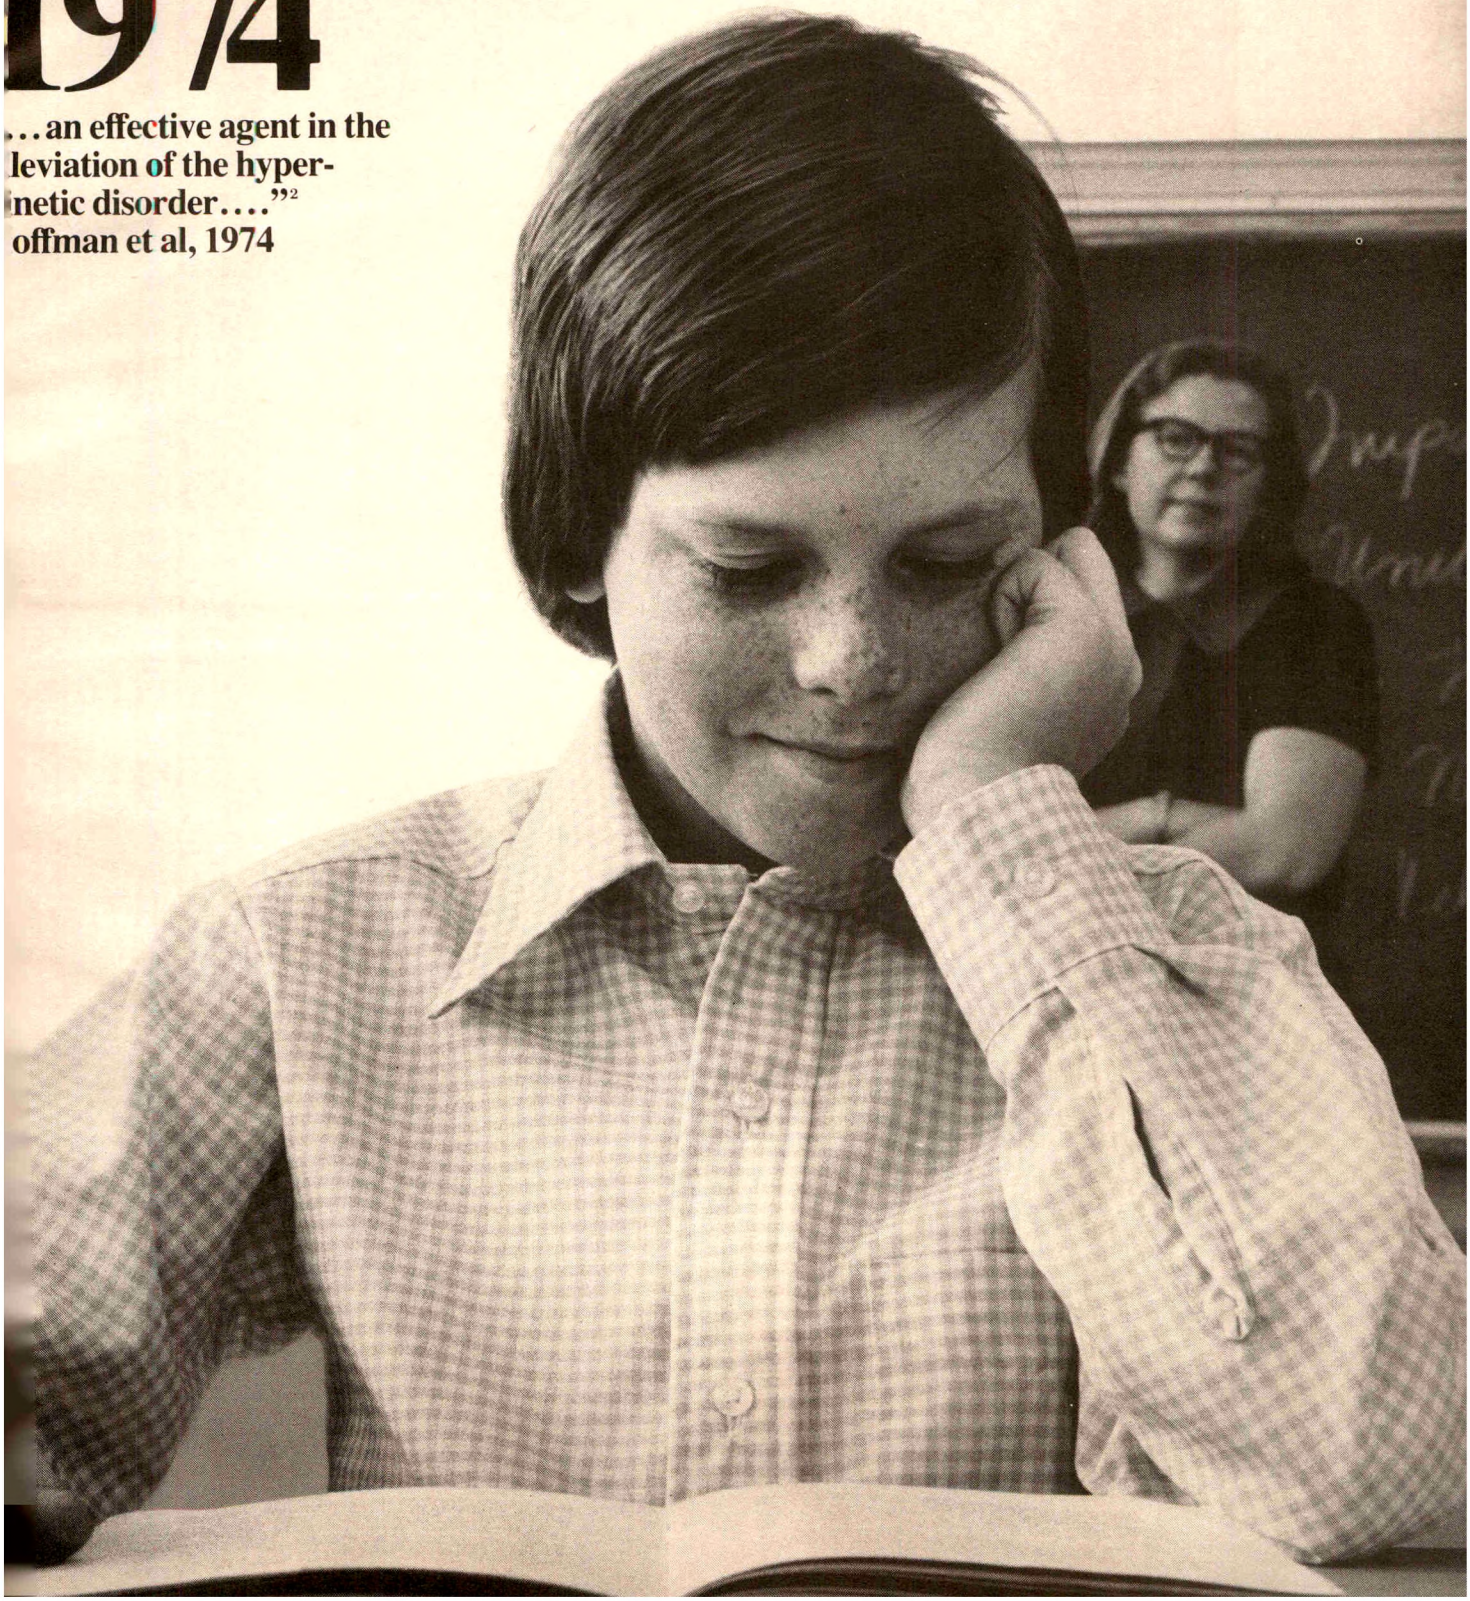
Over a decade of controlled studies and clinical experience has shown the effectiveness of Ritalin in reducing the hyperactivity,[1-3] distractibility,[1,4,5] and disorganized behavior[1-8] in the MBD child.

By lessening the effects of motor and attentional disorders, Ritalin can help the MBD child to better focus his attention on meaningful stimuli and thus can often improve cognition and promote learning.[6,9]

And side effects – insomnia and appetite loss – with Ritalin have occurred less frequently than with dextroamphetamine.[10,11]

Indeed, Ritalin is currently a drug of choice in many MBD situations,[10,12] and can prove to be an important element in many complete remedial programs for MBD.

Therapy with Ritalin should be undertaken only after a medical diagnosis of MBD has been made. Drug treatment is not indicated for all children with MBD.



Dosage should be periodically interrupted. Often, these interruptions reveal some "stabilization" in the child's behavior even without medication, permitting a reduction in dosage and eventual discontinuance of drug therapy.

TABLETS

INDICATION

Minimal Brain Dysfunction in Children—as adjunctive therapy to other remedial measures (psychological, educational, social)

Special Diagnostic Considerations

Specific etiology of Minimal Brain Dysfunction (MBD) is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources. Characteristics commonly reported include: chronic history of short attention span, distractibility, emotional lability, impulsivity, and moderate to severe hyperactivity; minor neurological signs and abnormal EEG. Learning may or may not be impaired. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with MBD. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis. Appropriate educational placement is essential and psychosocial intervention is generally necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.

CONTRAINDICATIONS

Marked anxiety, tension, and agitation, since Ritalin may aggravate these symptoms. Also contraindicated in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS

Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.

Sufficient data on safety and efficacy of long-term use of Ritalin in children with minimal brain dysfunction are not yet available.

Although a causal relationship has not been established, suppression of growth (*ie*, weight gain and/or height) has been reported with long-term use of stimulants in children. Therefore, children requiring long-term therapy should be carefully monitored.

Ritalin should not be used for severe depression of either exogenous or endogenous origin or for the prevention of normal fatigue states.

Ritalin may lower the convulsive threshold in patients with or without prior seizures; with or without prior EEG abnormalities, even in absence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. If seizures occur, Ritalin should be discontinued.

Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.

Symptoms of visual disturbances have been encountered in rare cases. Difficulties with accommodation and blurring of vision have been reported.

Drug Interactions

Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors. Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy

Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence

Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative. Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS

Patients with an element of agitation may react adversely; discontinue therapy if necessary. Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

ADVERSE REACTIONS

Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include: hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been reported. Although a definite causal relationship has not been established, the following have been reported in patients taking this drug: leukopenia and/or anemia; a few instances of scalp hair loss.

In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently; however, any of the other adverse reactions listed above may also occur.

DOSAGE AND ADMINISTRATION

Children with Minimal Brain Dysfunction (6 years and over)

Start with small doses (*eg*, 5 mg before breakfast and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-month period, the drug should be discontinued.

If paradoxical aggravation of symptoms or other adverse effects occur, reduce dosage, or, if necessary, discontinue the drug.

Ritalin should be periodically discontinued to assess the child's condition. Improvement may be sustained when the drug is either temporarily or permanently discontinued.

Drug treatment should not and need not be indefinite and usually may be discontinued after puberty.

HOW SUPPLIED

Tablets, 20 mg (peach, scored); bottles of 100 and 1000.

Tablets, 10 mg (pale green, scored); bottles of 100, 500, 1000 and Accu-Pak® blister units of 100.

Tablets, 5 mg (pale yellow); bottles of 100, 500 and 1000.

Consult complete product literature before prescribing.

Dome

New program for more than symptomatic control of the schizophrenic...

new from Dome Laboratories: a dual approach to help the schizophrenic adjust to a more normal life

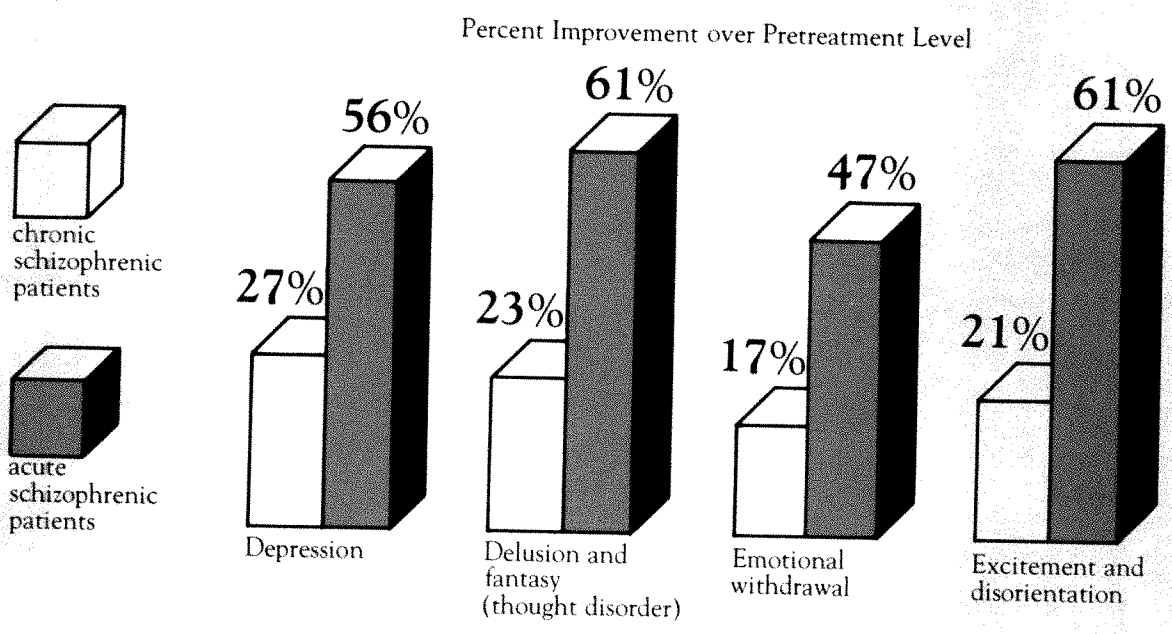
first... symptomatic help for the schizophrenic

Daxolin™
(loxapine succinate)

extensively investigated clinically

Loxapine succinate [Daxolin] has been studied clinically in both chronic and acute schizophrenic patients for over six years.[1-11]

evaluated by psychiatrists—BPRS (Brief Psychiatric Rating Scale), CGI (Clinical Global Impression)



evaluated by psychiatric nurses—NOSIE (Nurse's Observation Scale for Inpatient Evaluation)

evaluated by patients—SRSS (Self-Rating Symptom Scale)

compared with various other agents including chlorpromazine, trifluoperazine, doxepin, thiothixene, as well as placebo—from 11 published, controlled/double-blind studies involving 482 patients[1-11]

helps control symptoms of acute and chronic schizophrenia

Evaluation (by BPRS) of symptomatic response in 221 chronic and acute schizophrenic patients[12]

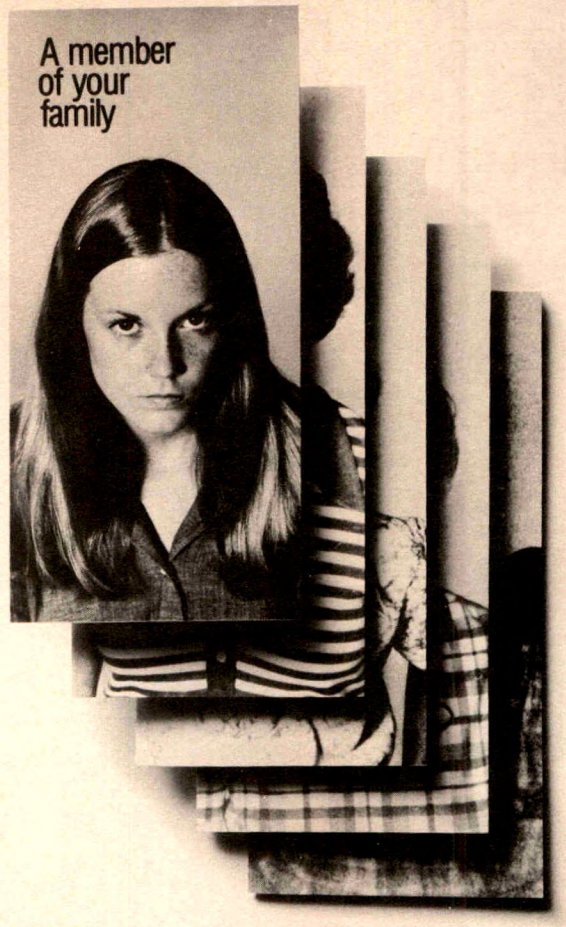
- ☐ significant improvement noted in behavior patterns, severity of symptoms significantly reduced
- ☐ helps control major target symptoms in responsive patients
- ☐ dosage strengths to meet individual needs
- ☐ adverse CNS manifestations—other than extrapyramidal reactions—infrequent*

***See "Adverse Reactions" section in the prescribing information on last page.**

and...

second... help for those close to the schizophrenic

EMP (EMPATHIC) COMMUNICATIONS



The symptoms of schizophrenia can be bizarre and puzzling—especially to family and others in close contact with the patient. To help them understand the disease, and thus be more helpful to the patient, Dome Laboratories offers *EMP* (Empathic) *Communications,* a comprehensive new education program developed especially for lay readers.

By providing authoritative, easy-to-understand booklets, this program encourages family and friends to cooperate in the patient's adjustment to therapy and rehabilitation.

...and for your information

PSYCHIATRIC INTERFACES

A new and ongoing publication of firsthand information that deals with current psychiatric trends and offers opinions on mental-health care from prominent psychiatrists.

EMP (EMPATHIC) COMMUNICATIONS
for the patient's family

The first in a series of booklets that answers a number of worrisome questions on how to cope with schizophrenia.

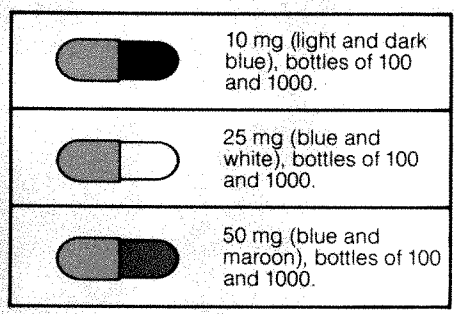
Other booklets offer specific information for *individual* members of the family and others in close contact with the patient, such as the employer, co-workers, paramedical personnel.

now...more than symptomatic control for the schizophrenic

EMP COMMUNICATIONS—an impressive educational program

PSYCHIATRIC INTERFACES—an outstanding information service

and



Daxolin™
(loxapine succinate)

a promising neuroleptic agent for symptomatic control of schizophrenia

See next page for prescribing information.

Daxolin™ (loxapine succinate)

individualized dosage strengths to meet the varying needs of the schizophrenic

10 mg (light and dark blue), bottles of 100 and 1000.

25 mg (blue and white), bottles of 100 and 1000.

50 mg (blue and maroon), bottles of 100 and 1000.

Description: DAXOLIN (loxapine succinate), a dibenzoxazepine compound, represents a new subclass of tricyclic antipsychotic agent, chemically distinct from the thioxanthenes, butyrophenones, and phenothiazines. Chemically, it is 2-chloro-11-(4-methyl-1-piperazinyl) dibenz[b,f][1,4] oxazepine. It is present in capsules as the succinate salt. Each 1.36 mg of loxapine succinate is equivalent to 1 mg of loxapine.

Actions: Pharmacologically, loxapine is a tranquilizer for which the exact mode of action has not been established. However, changes in the level of excitability of subcortical inhibitory areas have been observed in several animal species in association with such manifestations of tranquilization as calming effects and suppression of aggressive behavior.

In normal human volunteers, signs of sedation were seen within 20 to 30 minutes after administration, were most pronounced within 1½ to 3 hours, and lasted through 12 hours. Similar onset and duration of primary pharmacologic effect was seen in animals.

Absorption of loxapine following oral or parenteral administration is virtually complete. The drug is removed rapidly from the plasma and distributed in tissues. Animal studies suggest an initial preferential distribution in lungs, brain, spleen, heart, and kidney. Loxapine is metabolized extensively and excreted mainly in the first 24 hours. Metabolites are excreted in the urine in the form of conjugates but are unconjugated in the feces.

Indications: DAXOLIN is indicated for the manifestations of schizophrenia.

Contraindications: DAXOLIN (loxapine succinate) is contraindicated in comatose or severe drug-induced depressed states (alcohol, barbiturates, narcotics, etc.).

DAXOLIN is contraindicated in individuals with known hypersensitivity to the drug.

Warnings: *Usage in Pregnancy:* Safe use of DAXOLIN during pregnancy or lactation has not been established; therefore, its use in pregnancy, in nursing mothers, or in women of childbearing potential requires that the benefits of treatment be weighed against the possible risks to mother and child. No embryotoxicity or teratogenicity was observed in studies in rats, rabbits or dogs. With the exception of one rabbit study, the highest dosage was two times the maximum recommended human dose and in some studies the dose was lower. Perinatal studies have shown renal papillary abnormalities in offspring of rats treated from mid-pregnancy with doses of 0.6 and 1.8 mg/kg doses which approximate the usual human dose but which are considerably below the maximum recommended human dose.

Usage in Children: Studies have not been performed in children; therefore this drug is not recommended for use in children below the age of 16.

DAXOLIN, like other tranquilizers, may impair mental and/or physical abilities, especially during the first few days of therapy. Therefore, ambulatory patients should be warned about activities requiring alertness (eg, operating vehicles or machinery), and about concomitant use of alcohol and other CNS depressants.

Precautions: DAXOLIN should be used with extreme caution in patients with a history of convulsive disorders since it lowers the convulsive threshold. Seizures have been reported in epileptic patients receiving DAXOLIN at antipsychotic dose levels, and may occur even with maintenance of routine anticonvulsant drug therapy.

Loxapine has an antiemetic effect in animals. Since this effect also may occur in man, loxapine may mask signs of overdosage of toxic drugs and obscure conditions such as intestinal obstruction and brain tumor.

DAXOLIN should be used with caution in patients with cardiovascular disease. Increased pulse rates have been reported in the majority of patients receiving antipsychotic doses; and transient hypotension has been reported. In the presence of severe hypotension requiring vasopressor therapy, the preferred drugs may be norepinephrine or angiotensin. Usual doses of epinephrine may be ineffective because of inhibition of its vasopressor effect by loxapine.

The possibility of ocular toxicity from loxapine cannot be excluded at this time. Therefore, careful observation should be made for pigmentary retinopathy and lenticular pigmentation since these have been observed in some patients receiving certain other antipsychotic drugs for prolonged periods.

Because of possible anticholinergic action, the drug should be used cautiously in patients with glaucoma or a tendency to urinary retention, particularly with concomitant administration of anticholinergic-type antiparkinsonian medication.

Adverse Reactions: *CNS Effects:* Manifestations of adverse effects on the central nervous system, other than extrapyramidal effects, have been seen infrequently. Drowsiness, usually mild, may occur at the beginning of therapy or when dosage is increased. It usually subsides with continued DAXOLIN (loxapine succinate) therapy. The incidence of sedation has been less than that of certain aliphatic phenothiazines and slightly more than the piperazine phenothiazines. Dizziness, faintness, staggering gait, muscle twitching, weakness, and confusional states have been reported.

Extrapyramidal Reactions—Neuromuscular (extrapyramidal) reactions during the administration of DAXOLIN have been reported frequently, often during the first few days of treatment. In most patients, these reactions involved parkinsonism-like symptoms such as tremor, rigidity, excessive salivation, and masked facies. Akathisia (motor restlessness) also has been reported relatively frequently. These symptoms are usually not severe and can be controlled by reduction of DAXOLIN dosage or by administration of antiparkinsonian drugs in usual dosage. Dystonic and dyskinetic reactions have occurred less frequently, but may be more severe. Dystonias include spasms of muscles of the neck and face, tongue protrusion, and oculogyric movement. Dyskinetic reaction has been described in the form of choreoathetoid movements. These reactions sometimes require reduction or temporary withdrawal of DAXOLIN dosage in addition to appropriate counteractive drugs.

Persistent Tardive Dyskinesia—In keeping with the action of all antipsychotic agents, tardive dyskinesia may appear in some patients on long-term therapy or may appear after drug therapy has been discontinued. The risk appears to be greater in elderly patients—especially females—on high-dose therapy. The symptoms are persistent and, in some patients, appear to be irreversible. The syndrome is characterized by rhythmical involuntary movement of the tongue, face, mouth, or jaw (eg, protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of the extremities.

There is no known effective treatment for tardive dyskinesia; antiparkinsonian agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been suggested that fine vermicular movements of the tongue may be an early sign of the syndrome; if the medication is stopped at that time the syndrome may not develop.

Cardiovascular Effects: Tachycardia, hypotension, hypertension, light-headedness, and syncope have been reported. A few cases of ECG changes similar to those seen with phenothiazines have been reported. It is not known whether these were related to loxapine administration.

Skin Effects: Dermatitis, edema (puffiness of face), pruritus, and seborrhea have been reported with loxapine. The possibility of photosensitivity and/or phototoxicity occurring has not been excluded; skin rashes of uncertain etiology have been observed in a few patients during hot summer months.

Endocrine Effects: No endocrine abnormalities have been reported.

Anticholinergic Effects: Dry mouth, nasal congestion, constipation, and blurred vision have occurred; these are more likely to occur with concomitant use of antiparkinsonian agents.

Other Adverse Reactions: Nausea, vomiting, weight gain, weight loss, dyspnea, ptosis, hyperpyrexia, flushed facies, headache, paresthesia, and polydipsia have been reported in some patients.

Dosage and Administration: DAXOLIN (loxapine succinate) is administered orally, usually in divided doses, two to four times a day. Daily dosage (in terms of base equivalents) should be adjusted to the individual patient's needs as assessed by the severity of symptoms and previous history of response to antipsychotic drugs. Initial dosage of 10 mg twice daily is recommended although, in severely disturbed patients, initial dosage up to a total of 50 mg daily may be desirable. Dosage should then be increased fairly rapidly over the first seven to ten days until there is effective control of psychotic symptoms. The usual therapeutic and maintenance range is 60 mg to 100 mg daily. However, as with other antipsychotic drugs, some patients respond to lower dosage and others require higher dosage for optimal benefit. Daily dosage higher than 250 mg is not recommended. For maintenance therapy, dosage should be reduced to the lowest level compatible with symptom control; many patients have been maintained satisfactorily at dosages in the range of 20 mg to 60 mg daily.

How Supplied: DAXOLIN™ (loxapine succinate) is supplied in the following base-equivalent strengths:

CAPSULES Hard Shell Printed "DOME"

10 mg—Light and Dark Blue; bottles of 100 and 1000.

25 mg—Blue and White; bottles of 100 and 1000.

50 mg—Blue and Maroon; bottles of 100 and 1000.

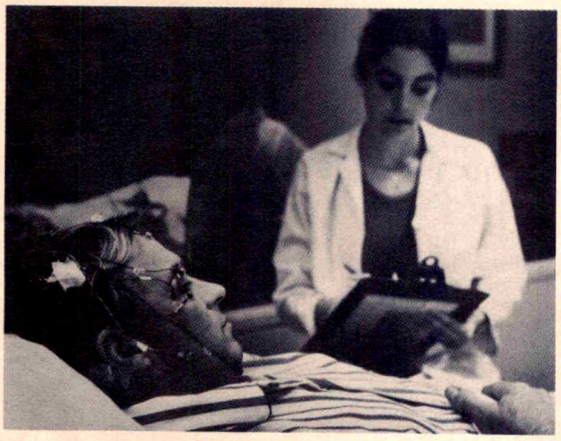
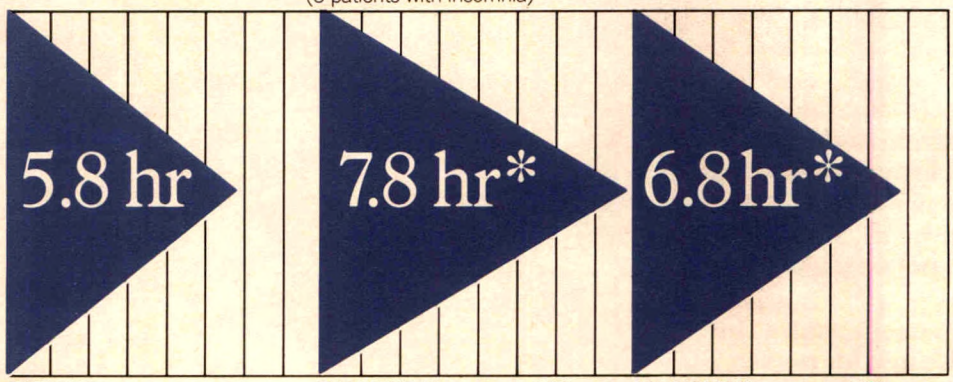
From the sleep research laboratory:



Dalmane® (flurazepam HCl) proved the most effective hypnotic over 14 nights...[1]

14 consecutive nights:
3 in sleep laboratory, 8 at home,
3 in sleep laboratory

...and now, the only one proven effective over 28 nights.[2,3]



28 consecutive nights:
3 in sleep laboratory, 7 at home,
4 in sleep laboratory, 10 at home,
4 in sleep laboratory[3]

For those patients who need it, Dalmane (flurazepam HCl) alone provides continued effectiveness[2,3]

Since insomnia is often transient and intermittent, the prolonged administration of a hypnotic is generally not necessary or recommended. But for those patients whose insomnia is a chronic problem, the continued effectiveness of Dalmane is a decided benefit. Even at the end of a 28-night medication period, patients with chronic insomnia were falling asleep faster, spending less time awake during the night, and sleeping substantially longer on Dalmane 30 mg *h.s.* than on baseline placebo nights (average results). This effectiveness was proved[2] and confirmed[3] in two independent sleep research studies using a new 47-night protocol. When similarly evaluated, pentobarbital was ineffective at the end of two weeks.[2]

TOTAL SLEEP TIME (MEAN)[3]
(5 patients with insomnia)

*Significantly increased over baseline placebo ($P < .05$).

In previous studies[1] chloral hydrate and glutethimide lost most or all effectiveness

In fact, continued effectiveness for both inducing and maintaining sleep over 14 consecutive nights[1] has long been an exclusive benefit of Dalmane. No other available sleep agent, including chloral hydrate or glutethimide,[1] has been able to demonstrate such effectiveness in the sleep research laboratory.

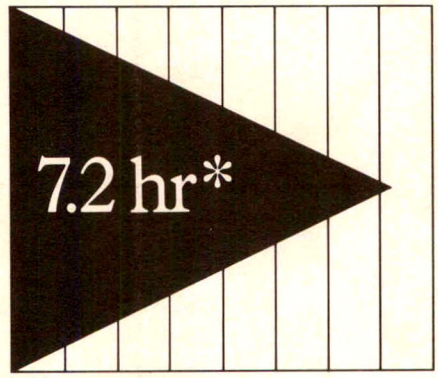
The safety record of Dalmane (flurazepam HCl) is well established

Dalmane is relatively safe and well tolerated. Prolonged administration is not generally necessary, but if used repeatedly, periodic blood counts and liver and kidney function tests should be performed.

Dalmane®
(flurazepam HCl)

ROCHE

relatively safe... no need to increase dosage.



Please see following page for a summary of complete product information.

1,5,7,14,28 nights... as needed, the effectiveness of **Dalmane**® one *h.s.* (flurazepam HCl) Ⓒ IV meets the challenge of insomnia

One 30-mg capsule *h.s.*—usual adult dosage (15 mg may suffice in some patients).
One 15-mg capsule *h.s.*—initial dosage for elderly or debilitated patients.

- **Patients fall asleep rapidly, sleep longer on a single *h.s.* dose.**
- **Nighttime awakenings and time spent awake are reduced**
- **Effectiveness maintained without dosage increase from night to night**
- **Patients generally awaken refreshed; morning "hangover" is infrequent**

TOTAL SLEEP TIME (OVERALL MEAN)[3]
(5 patients with insomnia)

DALMANE (flurazepam HCl)
NIGHTS 1-3, 12-14, 26-28

Before prescribing Dalmane (flurazepam HCl), please consult complete product information, a summary of which follows:

Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening; in patients with recurring insomnia or poor sleeping habits; and in acute or chronic medical situations requiring restful sleep. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended.

Contraindications: Known hypersensitivity to flurazepam HCl.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Use in women who are or may become pregnant only when potential benefits have been weighed against possible hazards. Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage.

Precautions: In elderly and debilitated, initial dosage should be limited to 15 mg to preclude oversedation, dizziness and/or ataxia. If combined with other drugs having hypnotic or CNS-depressant effects, consider potential additive effects. Employ usual precautions in patients who are severely depressed, or with latent depression or suicidal tendencies. Periodic blood counts and liver and kidney function tests are advised during repeated therapy. Observe usual precautions in presence of impaired renal or hepatic function.

Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported were headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, and elevated SGOT, SGPT, total and direct bilirubins and alkaline phosphatase. Paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity, have also been reported in rare instances.

Dosage: Individualize for maximum beneficial effect. *Adults:* 30 mg usual dosage; 15 mg may suffice in some patients. *Elderly or debilitated patients:* 15 mg initially until response is determined.

Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

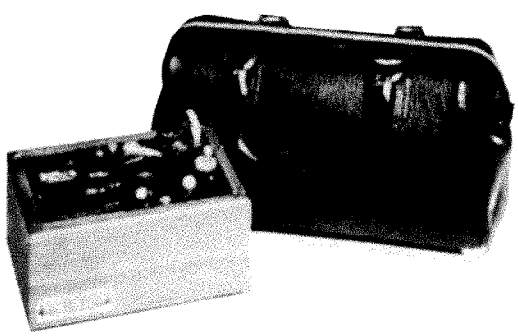
*Significantly increased over baseline placebo ($P < .05$)

MORE THAN 30 YEARS...

have proven the dependability and effectiveness of REITER ELECTROSTIMULATORS in psychiatry! Research and constant improvements to meet the standards of improved techniques have kept Reiter instruments

THE WORLD'S MOST ACCEPTED ELECTROSTIMULATORS

The Two Popular Models— **PORTABLE FOR OFFICE AND CLINIC**



The Reiter MODEL SOS—THE ONE INSTRUMENT FOR ALL ESTABLISHED TECHNIQUES, provides the fullest range of safest therapies. For painless, gentle stimulation of the conscious patient to relieve anxiety, depression, etc. Maximum safety, no additives—patient conscious and cooperating with therapy.

The SOS has also been used universally for Convulsive Therapy, Non-Convulsive Therapies, Electro-Sleep Therapy, Focal Treatment, Mono-Polar Treatment, Barbiturate Coma (and other respiratory problems), Mild Sedac, Deep Sedac Therapy, Pre-Convulsive Sedac, Post-Convulsive Sedac, Neurological Conditions, and Measurement Procedures.

Available with this redesigned model, on request, the following special-purpose electrodes —a Multi-Polar "Collar" type for Sleep Therapy, a "Horseshoe" assembly for quicker, surer application with one hand at last moment before ECT treatment, and a "Unilateral" type assembly.

Also built-in on request, an **automatic switch** for quicker build up to therapeutic ranges of Sedac.

SPECIAL MODEL SOS available without unidirectional convulsive current.

The Reiter Compact MOL-AC II—The smallest, lightest, least expensive and most reliable, clinically proven A.C. shock therapy instrument. Less confusion than from similar A.C. equipment. Now available with redesigned, improved panel. This compact instrument is only 3 x 5 inches, weighs but 3 lbs., yet provides full positive control of glisando effect over entire voltage range, as well as a positive manual control of time. There are NO complicated settings of dials, NO waiting for resetting of time devices, no warm-up delays.

An officially approved, extremely durable instrument which has earned world-wide professional acceptance, the MOL-AC II is economically priced with a fine, genuine leather physician's bag included.

Other Models Still Available: The CW47, original therapeutic cerebral stimulator with only 3 of the 9 treatment current selections available on Model SOS.

THE AMERICAN JOURNAL OF PSYCHIATRY

In this issue

A Bicentennial Address:
Benjamin Rush and Those
Who Came After Him
By Francis J. Braceland

OFFICIAL JOURNAL OF THE
AMERICAN PSYCHIATRIC ASSOCIATION

One of a series from "The Many Faces of

STELAZINE®
brand of
trifluoperazine HCl
in Psychiatry,"
a transcultural look at masks as symbols

Eskimo Finger Mask, Koskokwin River, Alaska.
Used by shaman as wand to drive out evil spirits.
Also used by women in ceremonial dances.

From the collection of the University Museum,
University of Pennsylvania, Philadelphia, Pa.
Reproduced with permission.

LIFT THE MASK OF SCHIZOPHRENIC SYMPTOMS

'Stelazine' provides effective control of hallucinations, delusions, anxiety and other psychotic symptoms.
With its apparent activating effect, 'Stelazine' is especially useful in withdrawn, apathetic or detached patients.

- Controls psychotic symptoms
- Seldom causes excessive sedation
- Convenient b.i.d. dosage

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications
Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information FDA has classified the indications as follows:

Effective: For the management of the manifestations of psychotic disorders.

Possibly effective: To control excessive anxiety, tension and agitation as seen in neuroses or associated with somatic conditions.

'Stelazine' has not been shown effective in the management of behavioral complications in patients with mental retardation.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; blood dyscrasias; bone marrow depression; liver damage.

Warnings: Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy.

Use in pregnancy only when necessary for patient's welfare.

Precautions: Use cautiously in angina. Avoid high doses and parenteral administration when cardiovascular system is impaired. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Additive effect is possible with other C.N.S. depressants. Prolonged administration of high doses may result in cumulative effects with severe C.N.S. or vasomotor symptoms. If retinal changes occur, discontinue drug. Agranulocytosis, thrombocytopenia, pancytopenia, anemia, cholestatic jaundice, liver damage have been reported.

Adverse Reactions: Drowsiness, dizziness, skin reactions, rash, dry mouth, insomnia, amenorrhea, fatigue, muscular weakness, anorexia, lactation, blurred vision. Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, persistent tardive dyskinesia.

Other adverse reactions reported with Stelazine (trifluoperazine HCl, SK&F*) or other phenothiazines:* Some adverse effects are more frequent or intense in specific disorders (e.g., mitral insufficiency or pheochromocytoma).

Grand mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat, and organophosphorus insecticides; nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, inhibition of ejaculation; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; leukopenia, eosinophilia, pancytopenia, agranulocytosis, thrombocytopenic purpura; jaundice, biliary stasis; menstrual irregularities, galactorrhea, gynecomastia, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits. EKG changes have been reported, but relationship to myocardial damage is not confirmed. Discontinue long-term, high-dose therapy gradually. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 1 mg., 2 mg., 5 mg., and 10 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only); Injection, 2 mg./ml.; and Concentrate (intended for institutional use only) 10 mg./ml.

Information for Contributors

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in duplicate to Francis J. Braceland, M.D., Editor, *The American Journal of Psychiatry*, 1700 Eighteenth Street, N.W., Washington, D.C. 20009. Authors of numbered papers presented at the Association's annual meeting should submit two copies of the manuscript to the secretary of the session or notify the secretary that the manuscript will be sent to the *Journal* office later.

All numbered annual meeting papers become the property of the *Journal* although, due to space limitations, fewer than half can be published in the *Journal*. Release of a manuscript for publication elsewhere must be secured from the Editor.

Communications about a manuscript, by letter or telephone, should include reference to the manuscript number. In the case of annual meeting papers, this is the number carried in the program booklet; with other manuscripts, it is the number noted in the letter acknowledging receipt of the manuscript.

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material and that they are not being considered for publication elsewhere. Once a paper has been published in the *Journal*, which is a copyrighted publication, the legal ownership of all parts of the paper, including any illustrations, passes from the author to the *Journal*. If an individual or organization wishes to reprint material published in the *Journal*, written permission must first be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Washington, D.C. 20009; there will usually be a charge for granting this permission.

Informed consent. Manuscripts that report the results of experimental investigation on human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure had been fully explained.

Manuscripts are accepted on condition that the Editor be given the right to make revisions aimed at greater conciseness and clarity and to bring the manuscript into conformity with *Journal* style regarding capitalization, punctuation, etc.

All measurements must be in metric units.

The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not reflect the official attitude or position of the American Psychiatric Association or of the *Journal's* Editorial Board.

SPECIFICATIONS FOR MANUSCRIPTS

Manuscripts should be typed in upper and lower case on one side only of letter-size bond (or other opaque) paper. All parts of the manuscript (including case reports, footnotes, references, etc.) should be double-spaced, with generous margins. Subheads should be inserted at reasonable intervals. Abbreviations not easily recognized by the average reader should be explained.

Length. As a general rule the manuscript of a regular article should not exceed 10–12 typed pages, unless a special arrangement has been made with the Editor; Brief Communications should not exceed 8 typed pages. Letters to the Editor should not exceed 500 words unless a special arrangement has been made with the Editor.

Author identification. The authors' affiliations and position titles should be provided and an address and telephone number given for the first-named author or the coauthor who has been designated to assume responsibility for the paper and reprint requests. The number of authors should be limited to principal researchers and writers, with other collaborators being acknowledged in a footnote.

Precis. A brief precis is included at the beginning of each article: 60–100 words for regular articles, 40–60 words for Brief Communications. The author may prepare the precis himself or ask that the *Journal* staff prepare it.

References. References should be typed double-spaced on a separate sheet of paper, to be attached at the end of the manuscript. They should be arranged according to their order of appearance in the text, where they should be indicated by numbers in parentheses. Reference citations should be restricted to closely pertinent papers; a complete review of the literature is rarely desirable, except in the case of review articles for which a special arrangement has been made with the Editor.

References should be typed in accordance with the style shown below for books and journal articles; chapters in books will be treated as journal articles with regard to capitalization. Up to three authors should be listed; one or more authors past the third will be designated "et al." Abbreviations of journal names should conform to the syle used in *Index Medicus*.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Schildkraut JJ: Tranylcypromine: effects on norepinephrine metabolism in rat brain. Am J Psychiatry 126:925–931, 1970
3. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349–365, 1967
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968, pp 1–12

Tables and figures. Tables and figures should be self-explanatory and should supplement, not duplicate, the text. See recent issues of the *Journal* for the general requirements of style.

Each table should be typed on a separate sheet, attached at the end of the manuscript. The data should be arranged so that columns of like material read down, not across.

A complete set of figures, preferably in the form of glossy prints, should accompany each of the two copies of the paper. Most figures will be reduced to about 3¼ inches in width; all elements of a figure should be prepared to withstand this reduction. Graphs should be finished drawings not requiring further artwork. Authors are urged to engage the services of a professional in the preparation of figures. Authors may be required to meet the costs of any further artwork that must be done in the editorial office.

AUTHORS' CORRECTIONS

After the paper has been scheduled for publication, the edited manuscript will be sent to the first-named author for corrections and answers to queries. Prompt return is necessary to ensure publication in the assigned month. If an author expects to be away from his office for a long period of time after being notified of the acceptance of his paper, he should inform the *Journal* office or arrange with a coauthor to assume responsibility for the paper. Galley proofs will not be sent to authors.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to authors prior to publication of their papers. Reprints are usually mailed to authors about a month after publication of the article. Requests from others to order reprints should be directed to the Editor; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such requests.

For the patient who needs a UNIQUE CONCEPT in MEDICAL and HOSPITAL CARE.

Las Encinas Hospital

Under complete supervision and direction of its Medical Staff, Las Encinas Hospital offers evaluation and treatment of a patient's total individual needs . . . psychological and physical.

A full time staff of Board certified specialists in Psychiatry, Internal Medicine, Radiology and Psychology, backed by a fully equipped and accredited hospital facility, offers clinical study, diagnosis, and long or short term care. All in a decidedly unhospital-like atmosphere of restful beauty, comfort, privacy and security. Rooms, suites and cottage accommodations available.

Write for our Illustrated Booklet:

  By Andre P. Derdeyn

Dome

New program for more than symptomatic control of the schizophrenic...

new from Dome Laboratories: a dual approach to help the schizophrenic adjust to a more normal life

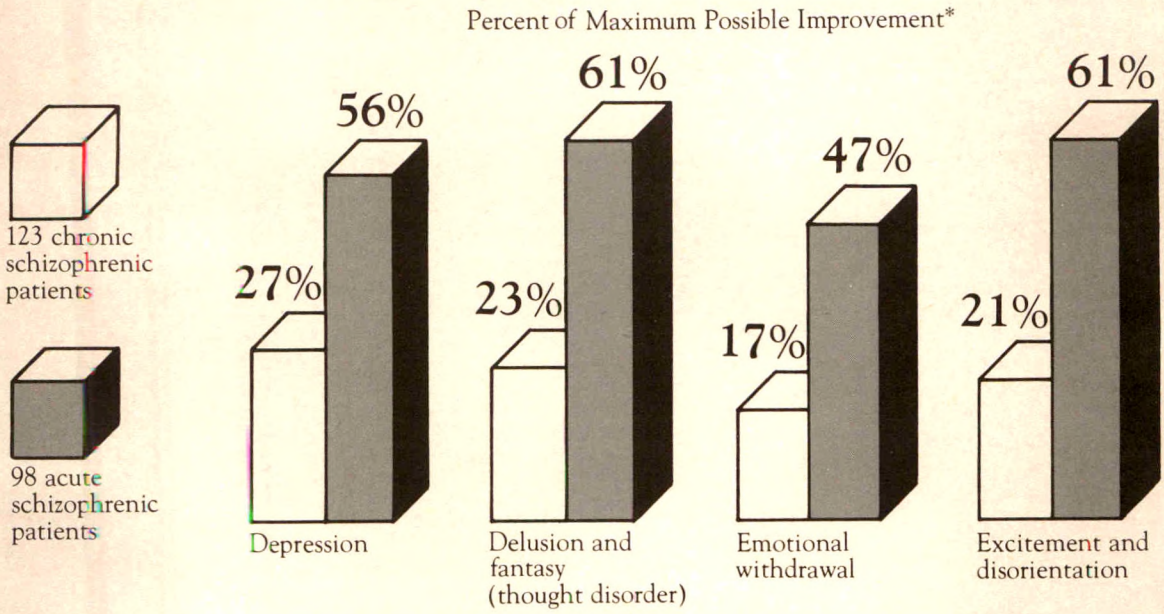
first...

symptomatic help for the schizophrenic

Daxolin®
(loxapine succinate)

extensively investigated clinically

Loxapine succinate [Daxolin] has been studied clinically in both chronic and acute schizophrenic patients.[1]



evaluated by psychiatrists—BPRS (Brief Psychiatric Rating Scale), CGI (Clinical Global Impression)

evaluated by psychiatric nurses—NOSIE (Nurse's Observation Scale for Inpatient Evaluation)

compared with various other agents including chlorpromazine, trifluoperazine, thiothixene, as well as placebo—from 11 published, controlled/double-blind studies involving 441 patients[1]

helps control symptoms of acute and chronic schizophrenia

Evaluation (by BPRS) of symptomatic response in 221 chronic and acute schizophrenic patients[1]

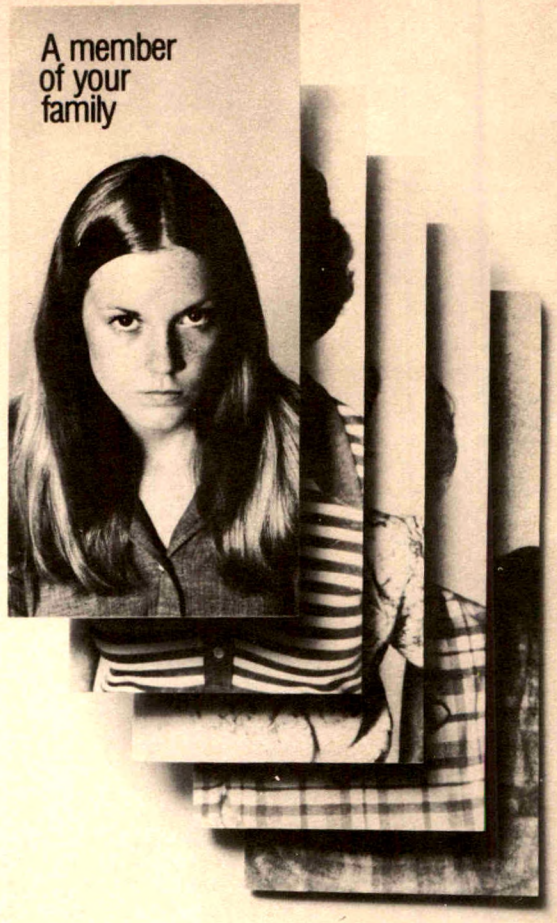
- ☐ significant improvement noted in behavior patterns, severity of symptoms significantly reduced
- ☐ helps control symptoms in responsive patients
- ☐ dosage strengths to meet individual needs
- ☐ manifestations of adverse effects on the central nervous system, other than extrapyramidal effects, have been seen infrequently.†

†See "Adverse Reactions" and "Actions" sections in the prescribing information on last page.

and...

second...
help for those close to the schizophrenic

EMP (EMPATHIC) COMMUNICATIONS



The symptoms of schizophrenia can be bizarre and puzzling—especially to family and others in close contact with the patient. To help them understand the disease, and thus be more helpful to the patient, Dome Laboratories offers *EMP* (Empathic) *Communications,* a comprehensive new education program developed especially for lay readers.

By providing authoritative, easy-to-understand booklets, this program encourages family and friends to cooperate in the patient's adjustment to therapy and rehabilitation.

...and for your information

PSYCHIATRIC INTERFACES

A new and ongoing publication of firsthand information that deals with current psychiatric trends and offers opinions on mental-health care from prominent psychiatrists.

EMP (EMPATHIC) COMMUNICATIONS
for the patient's family

The first in a series of booklets that answers a number of worrisome questions on how to cope with schizophrenia.

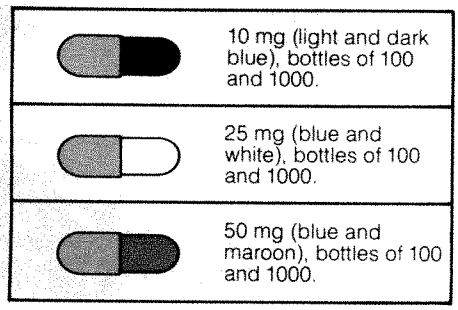
Other booklets offer specific information for *individual* members of the family and others in close contact with the patient, such as the employer, co-workers, paramedical personnel.

now...more than symptomatic control for the schizophrenic

EMP COMMUNICATIONS—an impressive educational program

PSYCHIATRIC INTERFACES—an outstanding information service

and



Daxolin®
(loxapine succinate)

a promising neuroleptic agent for symptomatic control of schizophrenia

See next page for prescribing information.

Daxolin® (loxapine succinate)

individualized dosage strengths to meet the varying needs of the schizophrenic

10 mg (light and dark blue), bottles of 100 and 1000.

25 mg (blue and white), bottles of 100 and 1000.

50 mg (blue and maroon), bottles of 100 and 1000.

Description: DAXOLIN (loxapine succinate), a dibenzoxazepine compound, represents a new subclass of tricyclic antipsychotic agent, chemically distinct from the thioxanthenes, butyrophenones, and phenothiazines. Chemically, it is 2-chloro-11-(4-methyl-1-piperazinyl) dibenz[b,f][1,4] oxazepine. It is present in capsules as the succinate salt. Each 1.36 mg of loxapine succinate is equivalent to 1 mg of loxapine.

Actions: Pharmacologically, loxapine is a tranquilizer for which the exact mode of action has not been established. However, changes in the level of excitability of subcortical inhibitory areas have been observed in several animal species in association with such manifestations of tranquilization as calming effects and suppression of aggressive behavior.

In normal human volunteers, signs of sedation were seen within 20 to 30 minutes after administration, were most pronounced within 1½ to 3 hours, and lasted through 12 hours. Similar onset and duration of primary pharmacologic effect was seen in animals.

Absorption of loxapine following oral or parenteral administration is virtually complete. The drug is removed rapidly from the plasma and distributed in tissues. Animal studies suggest an initial preferential distribution in lungs, brain, spleen, heart, and kidney. Loxapine is metabolized extensively and excreted mainly in the first 24 hours. Metabolites are excreted in the urine in the form of conjugates but are unconjugated in the feces.

Indications: DAXOLIN is indicated for the manifestations of schizophrenia.

Contraindications: DAXOLIN (loxapine succinate) is contraindicated in comatose or severe drug-induced depressed states (alcohol, barbiturates, narcotics, etc.).

DAXOLIN is contraindicated in individuals with known hypersensitivity to the drug.

Warnings: *Usage in Pregnancy:* Safe use of DAXOLIN during pregnancy or lactation has not been established; therefore, its use in pregnancy, in nursing mothers, or in women of childbearing potential requires that the benefits of treatment be weighed against the possible risks to mother and child. No embryotoxicity or teratogenicity was observed in studies in rats, rabbits or dogs. With the exception of one rabbit study, the highest dosage was two times the maximum recommended human dose and in some studies the dose was lower. Perinatal studies have shown renal papillary abnormalities in offspring of rats treated from mid-pregnancy with doses of 0.6 and 1.8 mg/kg doses which approximate the usual human dose but which are considerably below the maximum recommended human dose.

Usage in Children: Studies have not been performed in children; therefore this drug is not recommended for use in children below the age of 16.

DAXOLIN, like other tranquilizers, may impair mental and/or physical abilities, especially during the first few days of therapy. Therefore, ambulatory patients should be warned about activities requiring alertness (eg, operating vehicles or machinery), and about concomitant use of alcohol and other CNS depressants.

Precautions: DAXOLIN should be used with extreme caution in patients with a history of convulsive disorders since it lowers the convulsive threshold. Seizures have been reported in epileptic patients receiving DAXOLIN at antipsychotic dose levels, and may occur even with maintenance of routine anticonvulsant drug therapy.

Loxapine has an antiemetic effect in animals. Since this effect also may occur in man, loxapine may mask signs of overdosage of toxic drugs and obscure conditions such as intestinal obstruction and brain tumor.

DAXOLIN should be used with caution in patients with cardiovascular disease. Increased pulse rates have been reported in the majority of patients receiving antipsychotic doses; and transient hypotension has been reported. In the presence of severe hypotension requiring vasopressor therapy, the preferred drugs may be norepinephrine or angiotensin. Usual doses of epinephrine may be ineffective because of inhibition of its vasopressor effect by loxapine.

The possibility of ocular toxicity from loxapine cannot be excluded at this time. Therefore, careful observation should be made for pigmentary retinopathy and lenticular pigmentation since these have been observed in some patients receiving certain other antipsychotic drugs for prolonged periods.

Because of possible anticholinergic action, the drug should be used cautiously in patients with glaucoma or a tendency to urinary retention, particularly with concomitant administration of anticholinergic-type antiparkinsonian medication.

Adverse Reactions: *CNS Effects:* Manifestations of adverse effects on the central nervous system, other than extrapyramidal effects, have been seen infrequently. Drowsiness, usually mild, may occur at the beginning of therapy or when dosage is increased. It usually subsides with continued DAXOLIN (loxapine succinate) therapy. The incidence of sedation has been less than that of certain aliphatic phenothiazines and slightly more than the piperazine phenothiazines. Dizziness, faintness, staggering gait, muscle twitching,weakness,and confusional states have been reported.

Extrapyramidal Reactions—Neuromuscular (extrapyramidal) reactions during the administration of DAXOLIN have been reported frequently, often during the first few days of treatment. In most patients, these reactions involved parkinsonism-like symptoms such as tremor, rigidity, excessive salivation, and masked facies. Akathisia (motor restlessness) also has been reported relatively frequently. These symptoms are usually not severe and can be controlled by reduction of DAXOLIN dosage or by administration of antiparkinsonian drugs in usual dosage. Dystonic and dyskinetic reactions have occurred less frequently, but may be more severe. Dystonias include spasms of muscles of the neck and face, tongue protrusion, and oculogyric movement. Dyskinetic reaction has been described in the form of choreoathetoid movements. These reactions sometimes require reduction or temporary withdrawal of DAXOLIN dosage in addition to appropriate counteractive drugs.

Persistent Tardive Dyskinesia—In keeping with the action of all antipsychotic agents, tardive dyskinesia may appear in some patients on long-term therapy or may appear after drug therapy has been discontinued. The risk appears to be greater in elderly patients—especially females—on high-dose therapy. The symptoms are persistent and, in some patients, appear to be irreversible. The syndrome is characterized by rhythmical involuntary movement of the tongue, face, mouth, or jaw (eg, protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of the extremities.

There is no known effective treatment for tardive dyskinesia; antiparkinsonian agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been suggested that fine vermicular movements of the tongue may be an early sign of the syndrome; if the medication is stopped at that time the syndrome may not develop.

Cardiovascular Effects: Tachycardia, hypotension, hypertension, light-headedness, and syncope have been reported. A few cases of ECG changes similar to those seen with phenothiazines have been reported. It is not known whether these were related to loxapine administration.

Skin Effects: Dermatitis, edema (puffiness of face), pruritus, and seborrhea have been reported with loxapine. The possibility of photosensitivity and/or phototoxicity occurring has not been excluded; skin rashes of uncertain etiology have been observed in a few patients during hot summer months.

Endocrine Effects: No endocrine abnormalities have been reported.

Anticholinergic Effects: Dry mouth, nasal congestion, constipation, and blurred vision have occurred; these are more likely to occur with concomitant use of antiparkinsonian agents.

Other Adverse Reactions. Nausea, vomiting, weight gain, weight loss, dyspnea, ptosis, hyperpyrexia, flushed facies, headache, paresthesia, and polydipsia have been reported in some patients.

Dosage and Administration: DAXOLIN (loxapine succinate) is administered orally, usually in divided doses, two to four times a day. Daily dosage (in terms of base equivalents) should be adjusted to the individual patient's needs as assessed by the severity of symptoms and previous history of response to antipsychotic drugs. Initial dosage of 10 mg twice daily is recommended although, in severely disturbed patients, initial dosage up to a total of 50 mg daily may be desirable. Dosage should then be increased fairly rapidly over the first seven to ten days until there is effective control of psychotic symptoms. The usual therapeutic and maintenance range is 60 mg to 100 mg daily. However, as with other antipsychotic drugs, some patients respond to lower dosage and others require higher dosage for optimal benefit. Daily dosage higher than 250 mg is not recommended. For maintenance therapy, dosage should be reduced to the lowest level compatible with symptom control; many patients have been maintained satisfactorily at dosages in the range of 20 mg to 60 mg daily.

How Supplied: DAXOLIN™ (loxapine succinate) is supplied in the following base-equivalent strengths:
CAPSULES Hard Shell Printed "DOME"
10 mg—Light and Dark Blue; bottles of 100 and 1000.
25 mg—Blue and White; bottles of 100 and 1000.
50 mg—Blue and Maroon; bottles of 100 and 1000.

Out of touch

but not beyond reach...

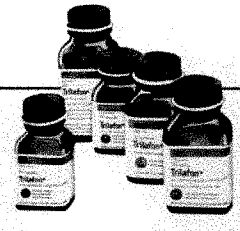
Help restore reality

Trilafon®

brand of perphenazine, NF

for management of disturbed behavior in schizophrenic and manic states

- low dose, high potency phenothiazine useful for inpatient and outpatient treatment
- helps orient psychiatric patients to their surroundings
- effective with minimal sedation, usually produces little lethargy or drowsiness



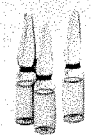
Versatile Dosage	
Injection	5 mg/ml, 1 ml ampul
Concentrate	16 mg/5 ml, 120 ml bottle
Tablets	2,4,8,16 mg
REPETABS® Tablets 8 mg brand of repeat-action tablets	

Please see next page for prescribing information.

Trilafon®
brand of perphenazine, NF

For management of schizophrenic and manic disorders in psychiatric hospitals, mental health clinics, and with outpatient treatment

TABLETS
for maintenance or control of patients in hospital or home



BENEFITS

- generally improve cooperation and communication
- decrease need for custodial care, hasten discharge

CONCENTRATE
for maintenance or control of uncooperative in-hospital patients

- easily mixes with most liquids
- ensures easy, steady, certain administration

INJECTION
for emergency control of uncooperative in-hospital patients

- usually takes effect in 10 minutes
- average duration of effect is 6 hours

TRILAFON® Tablets
brand of perphenazine, NF
REPETABS® Tablets
Concentrate
Injection

CONTRAINDICATIONS TRILAFON is contraindicated in drug-associated central nervous system depression (barbiturates, alcohol, narcotics, analgesics, antihistamines). Perphenazine is contraindicated in the presence of existing blood dyscrasias, bone marrow depression and pre-existing liver damage, and in patients who are hypersensitive to perphenazine.

TRILAFON **Injection** should not be given to patients in coma or severely depressed states.

WARNINGS **Dosage in pregnancy:** Perphenazine should only be given to pregnant patients when, in the judgment of the physician, the potential benefits outweigh the possible risks.

Perphenazine can lower the convulsive threshold in susceptible individuals; it should be used with caution in patients with convulsive disorders. If the patient is being treated with an anticonvulsant agent, increased dosage of that agent may be required when perphenazine is used concomitantly.

Perphenazine should be used with caution in patients with psychic depression.

Perphenazine is not recommended for children under 12 years of age.

Perphenazine may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks, such as driving a car or operating machinery.

PRECAUTIONS As with any potent medication, patients receiving perphenazine should be under medical supervision, particularly if they are receiving high doses. Patients who have had any severe reaction to phenothiazines or to imipramine should be treated cautiously, under close medical supervision.

Although the following adverse reactions have not been reported in patients treated with perphenazine, the possibility that they might occur with TRILAFON should be considered: blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, eosinophilia); liver damage (biliary stasis); narrowing of the visual fields; pigmentation of the retina, cornea, or lens; cerebral edema; polyphagia; photophobia; hyperpyrexia.

If hypotension develops, levarterenol (norepinephrine) can be used, but not epinephrine, because epinephrine's action is blocked and partly reversed by perphenazine. Severe, acute hypotension has occurred with the use of phenothiazines and is of particular concern in patients with mitral insufficiency or pheochromocytoma.

A significant rise in body temperature may indicate an idiosyncratic reaction to perphenazine; treatment with perphenazine should be stopped if this occurs.

The antiemetic effect of perphenazine can obscure signs of toxicity due to overdosage of other drugs, or mask the symptoms of disease (eg, brain tumor or intestinal obstruction).

Contact dermatitis has been reported with a perphenazine solution; therefore, contact of hands or clothing by those handling perphenazine solutions should be avoided.

POTENTIATION Since phenothiazines can potentiate the central-nervous-system-depressant actions of opiates, antihistamines, barbiturates, and alcohol, less than the usual dosage of these agents is required when they are administered concomitantly with TRILAFON. Patients should be cautioned that their response to alcohol may be increased while they are being treated with TRILAFON.

Phenothiazines also potentiate the effects of atropine, heat, and phosphorus insecticides, and should be used with caution in persons exposed to these agents.

ADVERSE REACTIONS *Extrapyramidal reactions:* dystonia including protrusion, discoloration, aching and rounding of the tongue; tonic spasm of the masticatory muscles, tight feeling in the throat, slurred speech, dysphagia, oculogyric crisis, trismus, torticollis, retrocollis, muscle weakness, and aching and numbness of the limbs; akathisia; motor restlessness; dyskinesia, parkinsonism; hyperreflexia; and ataxia. The incidence and severity of these reactions usually increase with increased dosage, but have occurred in some patients receiving low dosage. Reduction in dosage or treatment with an antispasmodic agent will usually control extrapyramidal reactions. In some instances, however, these reactions may persist after discontinuation of treatment with perphenazine.

Persistent tardive dyskinesia: As with all antipsychotic agents, tardive dyskinesia may appear in some patients on long-term therapy or may appear after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (eg, protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities. There is no known effective treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been reported that fine, vermicular movements of the tongue may be an early sign of the syndrome, and if the medication is stopped at that time the syndrome may not develop.

Allergic reactions: erythema, pruritus, urticaria, eczema, anaphylactoid reactions, and local and generalized edema. In extremely rare instances, individual idiosyncrasy or hypersensitivity to phenothiazines has resulted in cerebral edema, circulatory collapse, and death. Photosensitization, asthma, and exfoliative dermatitis have also occurred in patients treated with phenothiazines.

Autonomic reactions: blurred vision, dry mouth or salivation, nasal congestion, nausea, vomiting, hypertension, tachycardia, hypotension, anorexia, urinary frequency or incontinence, and constipation. Significant autonomic effects have been infrequent in patients receiving less than 24 mg. perphenazine daily.

Other reactions: endocrine disturbances (lactation, gynecomastia, galactorrhea, disturbances in the menstrual cycle), headaches, mild insomnia, altered cerebrospinal fluid proteins, ECG abnormalities, reactivation of psychosis, paradoxical excitement, paranoid-like reactions, catatonia, and systemic lupus erythematosus-like syndrome. Hypnotic effects appear to be minimal, particularly in patients who are permitted to remain active. The following adverse reactions, though rare, have also been reported to be associated with perphenazine treatment: agranulocytosis; jaundice; hyperpigmentation of the skin; grand mal convulsions; failure of ejaculation; hyperglycemia.

Side effects with intramuscular TRILAFON **Injection** have been infrequent and transient. Dizziness or significant hypotension after treatment with TRILAFON (perphenazine) **Injection** is a rare occurrence.

SINEQUAN®
DOXEPIN HCl

100-mg., 50-mg., 25-mg. Capsules and ORAL CONCENTRATE 10 mg./ml., 120-ml. (4-oz.) bottles

MAY BE AN APPROPRIATE CHOICE FOR YOUR NEXT PATIENT WITH CLINICAL DEPRESSION

See Brief Summary on last page of advertisement for information on adverse reactions, contraindications, warnings and precautions.

SINEQUAN®
DOXEPIN HCl

100-mg., 50-mg., 25-mg. Capsules and
ORAL CONCENTRATE 10 mg./ml., 120-ml. (4-oz.) bottles

Proved efficacy in the treatment of clinical depression

In the six years since its introduction, Sinequan (doxepin HCl) has objectively demonstrated its value in the treatment of clinical depression. Clinical studies have shown Sinequan to be unsurpassed in effectiveness when compared to other tricyclic antidepressants.

In addition, Sinequan may offer certain advantages not generally seen with some other drugs of its class:

Prompt sedative activity

Of the tricyclic antidepressants, Sinequan has been found to have one of the most prominent sedative effects.[1] This sedative property can be taken advantage of by administering the major portion of the daily dose *h.s.* Since clinically depressed patients frequently have accompanying sleep disturbances, this may be a valuable benefit.

Generally does not affect the activity of guanethidine at usual clinical doses[2]

"A new tricyclic antidepressant, doxepin, was evaluated for its ability to block the amine uptake mechanisms of the peripheral adrenergic neuron and blood platelet in man. At low doses, there was no evidence of inhibition of the amine pump." At clinical dosages up to 150 mg. per day, Sinequan can be given to man concomitantly with guanethidine and related compounds without blocking the antihypertensive effect.[2]

Cardiovascular effects, including hypotension and tachycardia, have been reported occasionally

In a series of double-blind comparative studies, 1,706 doxepin-treated patients were evaluated for side effects. Incidence of tachycardia was associated with only 45 (2.6%) clinically depressed/anxious patients. Incidence of symptomatic hypotension was associated with only 48 (2.8%) clinically depressed/anxious patients.[3]

SINEQUAN®
DOXEPIN HCl

100-mg., 50-mg., 25-mg. Capsules and
ORAL CONCENTRATE 10 mg./ml., 120-ml. (4-oz.) bottles

BRIEF SUMMARY
SINEQUAN® (doxepin HCl) Capsules/Oral Concentrate
Contraindications. Contraindicated in individuals who have shown hypersensitivity to the drug, and in patients with glaucoma or a tendency to urinary retention. Possibility of cross sensitivity with other dibenzoxepines should be kept in mind.
Warnings. The once-a-day dosage regimen of SINEQUAN in patients with intercurrent illness or patients taking other medications should be carefully adjusted. This is especially important in patients receiving other medications with anticholinergic effects.
Usage in Geriatrics: The use of SINEQUAN on a once-a-day dosage regimen in geriatric patients should be adjusted carefully based on the patient's condition.
Usage in Pregnancy: Reproduction studies performed in animals have shown no evidence of harm to the animal fetus. Since there is no experience in pregnant women receiving this drug, safety in pregnancy has not been established. There are no data with respect to the secretion of the drug in human milk and its effect on the nursing infant.
Usage in Children: Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.
MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug. The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered and the dosage involved.
Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug. Patients should also be cautioned that their response to alcohol may be potentiated.
Since suicide is an inherent risk in any depressed patient, and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy.
Should increased symptoms of psychosis or shift to manic symptomatology occur, it may be necessary to reduce dosage or add a major tranquilizer to the dosage regimen.
Adverse Reactions. NOTE: Some of the adverse reactions noted below have not been specifically reported with SINEQUAN use. However, due to the close pharmacological similarities among the tricyclics, the reactions should be considered when prescribing SINEQUAN.
Anticholinergic Effects: Dry mouth, blurred vision, constipation, and urinary retention have been reported. If they do not subside with continued therapy, or become severe, it may be necessary to reduce the dosage.
Central Nervous System Effects: Drowsiness is the most commonly noticed side effect. This tends to disappear as therapy is continued. Other infrequently reported CNS side effects are confusion, disorientation, hallucinations, numbness, paresthesias, ataxia, extrapyramidal symptoms and seizures.
Cardiovascular: Cardiovascular effects including hypotension and tachycardia have been reported occasionally.
Allergic: Skin rash, edema, photosensitization, and pruritus have occasionally occurred.
Hematologic: Eosinophilia has been reported in a few patients. There have been occasional reports of bone marrow depression manifesting as agranulocytosis, leukopenia, thrombocytopenia, and purpura.
Gastrointestinal: Nausea, vomiting, indigestion, taste disturbances, diarrhea, anorexia, and aphthous stomatitis have been reported. (See anticholinergic effects.)
Endocrine: Raised or lowered libido, testicular swelling, gynecomastia in males, enlargement of breasts and galactorrhea in the female, raising or lowering of blood sugar levels have been reported with tricyclic administration.
Other: Dizziness, tinnitus, weight gain, sweating, chills, fatigue, weakness, flushing, jaundice, alopecia, and headache have been occasionally observed as adverse effects.
Dosage and Administration. For most patients with illness of mild to moderate severity, a starting dose of 25 mg t.i.d. is recommended. Dosage may subsequently be increased or decreased at appropriate intervals and according to individual response. The usual optimum dose range is 75 mg/day to 150 mg/day.
In more severely ill patients an initial dose of 50 mg t.i.d. may be required with subsequent gradual increase to 300 mg/day if necessary. Additional therapeutic effect is rarely to be obtained by exceeding a dose of 300 mg/day.
In patients with very mild symptomatology or emotional symptoms accompanying organic disease, lower doses may suffice. Some of these patients have been controlled on doses as low as 25-50 mg/day.
As an alternative regimen, the total daily dosage, up to 150 mg, may be given on a once-a-day schedule without loss of effectiveness. This dose may be given at bedtime.
Anti-anxiety effect is apparent before the antidepressant effect. Optimal antidepressant effect may not be evident for two to three weeks.
Overdosage. A. Signs and Symptoms
1. Mild: Drowsiness, stupor, blurred vision, excessive dryness of mouth.
2. Severe: Respiratory depression, hypotension, coma, convulsions, cardiac arrhythmias and tachycardias.
Also: urinary retention (bladder atony), decreased gastrointestinal motility (paralytic ileus), hyperthermia (or hypothermia), hypertension, dilated pupils, hyperactive reflexes.
B. Management and Treatment
1. Mild: Observation and supportive therapy is all that is usually necessary.
2. Severe: Medical management of severe SINEQUAN overdosage consists of aggressive supportive therapy. If the patient is conscious, gastric lavage, with appropriate precautions to prevent pulmonary aspiration, should be performed even though SINEQUAN is rapidly absorbed. The use of activated charcoal has been recommended, as has been continuous gastric lavage with saline for 24 hours or more. An adequate airway should be established in comatose patients and assisted ventilation used if necessary. EKG monitoring may be required for several days, since relapse after apparent recovery has been reported. Arrhythmias should be treated with the appropriate antiarrhythmic agent. It has been reported that many of the cardiovascular and CNS symptoms of tricyclic antidepressant poisoning in adults may be reversed by the slow intravenous administration of 1 mg to 3 mg of physostigmine salicylate. Because physostigmine is rapidly metabolized, the dosage should be repeated as required. Convulsions may respond to standard anticonvulsant therapy; however, barbiturates may potentiate any respiratory depression. Dialysis and forced diuresis generally are not of value in the management of overdosage due to high tissue and protein binding of SINEQUAN.
Supply. Available as capsules containing doxepin HCl equivalent to 10 mg, 25 mg, 50 mg, and 100 mg doxepin in bottles of 100, 1000, and unit-dose packages of 100 (10 x 10's). SINEQUAN (doxepin HCl) 25 mg and 50 mg are also available in bottles of 5000. SINEQUAN Oral Concentrate is available in 120 ml bottles with an accompanying dropper calibrated at 5 mg, 10 mg, 15 mg, 20 mg, and 25 mg. Each ml contains doxepin HCl equivalent to 10 mg doxepin. Just prior to administration, SINEQUAN Oral Concentrate should be diluted with approximately 120 ml of water, whole or skimmed milk, or orange, grapefruit, tomato, prune or pineapple juice. SINEQUAN Oral Concentrate is not physically compatible with a number of carbonated beverages. For those patients requiring antidepressant therapy who are on methadone maintenance, SINEQUAN Oral Concentrate and methadone syrup can be mixed together with Gatorade®, lemonade, orange juice, sugar water, Tang®, or water; but not with grape juice. Preparation and storage of bulk dilutions is not recommended.

Loxitane®
LOXAPINE SUCCINATE
Lederle

From the record:

LOXITANE has favorable trends

exhibited certain in side effects profile

While cardiac arrest, blood dyscrasias and renal toxicity have been reported with other antipsychotic agents, they have not been seen with LOXITANE. Hepatotoxicity manifested by jaundice or biliary stasis has not been observed. Transient liver enzyme changes, however, have been reported, but it has not been determined whether they are related to LOXITANE administration.

Although a few cases of changes in ECG have been reported, a causal relationship between this reaction and LOXITANE has not been established. Clinical experience with LOXITANE has not demonstrated ocular toxicity, however, the possibility of its occurrence cannot be ruled out at this time. Of the various endocrine abnormalities, only galactorrhea has been noted with LOXITANE, and only in rare instances.

Manifestations of adverse effects on the central nervous system other than extrapyramidal symptoms have been encountered infrequently, and drowsiness, when it occurs, is usually mild and subsides with continued therapy. Skin rashes of uncertain etiology have been observed in a few patients during the hot summer months; therefore the possibility of phototoxicity and/or photosensitivity cannot be excluded. Like certain other antipsychotic agents, LOXITANE lowers the convulsive threshold and should be used with extreme caution in patients with a history of convulsive disorders.

In general, LOXITANE presents a profile of extrapyramidal side effects similar to that of other agents used in the treatment of schizophrenia.

Cardiovascular effects such as hypotension, hypertension, light-headedness and syncope have been reported. Anticholinergic effects seen with LOXITANE include dry mouth, nasal congestion, constipation and blurred vision.

See LOXITANE prescribing information on next page for contraindications, warnings and precautions and for more detailed information concerning side effects.

A range of dosage strengths to suit the patient's individual needs

Supplied

Capsules

10 mg Green and Yellow	
25 mg Green Two Tone	
50 mg Green and Blue	

Recommended Daily Dosage

Initial Dosage	MILD 10 mg b.i.d.	MODERATE 10 mg t.i.d. or q.i.d.	SEVERE 25 mg b.i.d.
First 7 to 10 Days	Increase dosage until psychotic symptoms are controlled. Dosage should not exceed 250 mg/day.		
	Usual dosage during titration: 50 to 150 mg/day.		
Maintenance Dosage	Adjust to lowest effective level.		
	Usual maintenance dosage: 60 to 100 mg/day.		
	Many patients are controlled with dosages as low as 20 to 60 mg/day.		

Loxitane®
LOXAPINE Lederle
SUCCINATE

Because efficacy and side effects are a single consideration

Loxitane®
LOXAPINE Lederle SUCCINATE

Because efficacy and side effects are a single consideration

FOR ORAL USE

DESCRIPTION

LOXITANE *loxapine*, a dibenzoxazepine compound, represents a new subclass of tricyclic antipsychotic agent, chemically distinct from the thioxanthenes, butyrophenones, and phenothiazines. Chemically, it is 2-chloro-11-(4-methyl-1-piperazinyl)dibenz[b,f] [1,4]oxazepine. It is present in capsules as the succinate salt. Each 1.36 mg. of loxapine succinate is equivalent to 1 mg. of loxapine.

ACTIONS

Pharmacologically, loxapine is a tranquilizer for which the exact mode of action has not been established. However, changes in the level of excitability of subcortical inhibitory areas have been observed in several animal species in association with such manifestations of tranquilization as calming effects and suppression of aggressive behavior.

In normal human volunteers, signs of sedation were seen within 20 to 30 minutes after administration, were most pronounced within 1½ to 3 hours, and lasted through 12 hours. Similar timing of primary pharmacologic effects was seen in animals.

Absorption of loxapine following oral or parenteral administration is virtually complete. The drug is removed rapidly from the plasma and distributed in tissues. Animal studies suggest an initial preferential distribution in lungs, brain, spleen, heart, and kidney. Loxapine is metabolized extensively and is excreted mainly in the first 24 hours. Metabolites are excreted in the urine in the form of conjugates and in the feces unconjugated.

INDICATIONS

LOXITANE *loxapine succinate* is indicated for the manifestations of schizophrenia.

LOXITANE has not been evaluated for the management of behavioral complications in patients with mental retardation, and therefore it cannot be recommended.

CONTRAINDICATIONS

LOXITANE is contraindicated in comatose or severe drug-induced depressed states (alcohol, barbiturates, narcotics, etc.)

LOXITANE is contraindicated in individuals with known hypersensitivity to the drug.

WARNINGS

Usage in Pregnancy—Safe use of LOXITANE *loxapine succinate* during pregnancy or lactation has not been established; therefore, its use in pregnancy, in nursing mothers, or in women of childbearing potential requires that the benefits of treatment be weighed against the possible risks to mother and child. No embryotoxicity or teratology was observed in studies in rats, rabbits or dogs, although with the exception of one rabbit study, the highest dosage was only two times the maximum recommended human dose and in some studies they were below this dose. Perinatal studies have shown renal papillary abnormalities in offspring of rats treated from mid-pregnancy with doses of 0.6 and 1.8 mg/kg, doses which approximate the usual human dose but which are considerably below the maximum recommended human dose.

Usage in Children—Studies have not been performed in children; therefore this drug is not recommended for use in children below the age of 16.

LOXITANE, like other tranquilizers, may impair mental and/or physical abilities, especially during the first few days of therapy. Therefore, ambulatory patients should be warned about activities requiring alertness (eg, operating vehicles or machinery), and about concomitant use of alcohol and other CNS depressants.

PRECAUTIONS

LOXITANE should be used with extreme caution in patients with a history of convulsive disorders since it lowers the convulsive threshold. Seizures have been reported in epileptic patients receiving LOXITANE at antipsychotic dose levels, and may occur even with maintenance of routine anticonvulsant drug therapy.

Loxapine has an antiemetic effect in animals. Since this effect may also occur in man, loxapine may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

LOXITANE should be used with caution in patients with cardiovascular disease. Increased pulse rates have been reported in the majority of patients receiving antipsychotic doses; transient hypotension has been reported. In the presence of severe hypotension requiring vasopressor therapy, the preferred drugs may be norepinephrine or angiotensin. Usual doses of epinephrine may be ineffective because of inhibition of its vasopressor effect by loxapine.

The possibility of ocular toxicity from loxapine cannot be excluded at this time. Therefore, careful observation should be made for pigmentary retinopathy and lenticular pigmentation since these have been observed in some patients receiving certain other antipsychotic drugs for prolonged periods.

Because of possible anticholinergic action, the drug should be used cautiously in patients with glaucoma or a tendency to urinary retention, particularly with concomitant administration of anticholinergic-type antiparkinson medication.

ADVERSE REACTIONS

CNS Effects—Manifestations of adverse effects on the central nervous system, other than extrapyramidal effects, have been seen infrequently. Drowsiness, usually mild, may occur at the beginning of therapy or when dosage is increased.

It usually subsides with continued LOXITANE therapy. The incidence of sedation has been less than that of certain aliphatic phenothiazines and slightly more than the piperazine phenothiazines. Dizziness, faintness, staggering gait, muscle twitching, weakness, and confusional states have been reported.

Extrapyramidal Reactions—Neuromuscular (extrapyramidal) reactions during the administration of LOXITANE *loxapine succinate* have been reported frequently, often during the first few days of treatment. In most patients, these reactions involved Parkinson-like symptoms such as tremor, rigidity, excessive salivation, and masked facies. Akathisia (motor restlessness) also has been reported relatively frequently. These symptoms are usually not severe and can be controlled by reduction of LOXITANE dosage or by administration of antiparkinson drugs in usual dosage. Dystonic and dyskinetic reactions have occurred less frequently, but may be more severe. Dystonias include spasms of muscles of the neck and face, tongue protrusion, and oculogyric movement. Dyskinetic reaction has been described in the form of choreo-athetoid movements. These reactions sometimes require reduction or temporary withdrawal of LOXITANE dosage in addition to appropriate counteractive drugs.

Persistent Tardive Dyskinesia—As with all antipsychotic agents, tardive dyskinesia may appear in some patients on long-term therapy or may appear after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movement of the tongue, face, mouth, or jaw (eg, protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia; antiparkinson agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been suggested that fine vermicular movements of the tongue may be an early sign of the syndrome, and if the medication is stopped at that time the syndrome may not develop.

Cardiovascular Effects—Tachycardia, hypotension, hypertension, lightheadedness, and syncope have been reported.

A few cases of ECG changes similar to those seen with phenothiazines have been reported. It is not known whether these were related to loxapine administration.

Skin—Dermatitis, edema (puffiness of face), pruritus, and seborrhea have been reported with loxapine. The possibility of photosensitivity and/or phototoxicity occurring has not been excluded; skin rashes of uncertain etiology have been observed in a few patients during hot summer months.

Anticholinergic Effects—Dry mouth, nasal congestion, constipation, and blurred vision have occurred; these are more likely to occur with concomitant use of antiparkinson agents.

Other Adverse Reactions—Nausea, vomiting, weight gain, weight loss, dyspnea, ptosis, hyperpyrexia, flushed facies, headache, paresthesia, and polydipsia have been reported in some patients. Rarely, galactorrhea and menstrual irregularity of uncertain etiology have been reported.

DOSAGE AND ADMINISTRATION

LOXITANE *loxapine succinate* is administered orally usually in divided doses two to four times a day. Daily dosage (in terms of base equivalents) should be adjusted to the individual patient's needs as assessed by the severity of symptoms and previous history of response to antipsychotic drugs. Initial dosage of 10 mg twice daily is recommended, although in severely disturbed patients initial dosage up to a total of 50 mg daily may be desirable. Dosage should then be increased fairly rapidly over the first seven to ten days until there is effective control of psychotic symptoms. The usual therapeutic and maintenance range is 60 mg to 100 mg daily. However, as with other antipsychotic drugs, some patients respond to lower dosage and others require higher dosage for optimal benefit. Daily dosage higher than 250 mg is not recommended. For maintenance therapy, dosage should be reduced to the lowest level compatible with symptom control; many patients have been maintained satisfactorily at dosages in the range of 20 mg to 60 mg daily.

HOW SUPPLIED

LOXITANE *loxapine succinate* is supplied in the following base equivalent strengths:

CAPSULES Hard Shell Printed "Lederle"

10 mg—Green and Yellow; Bottles of 100, 1000, and unit dose 10 x 10's—Product Number 5360.

25 mg—Green Two Tone; Bottles of 100, 1000, and unit dose 10 x 10's—Product Number 5361.

50 mg—Green and Blue; Bottles of 100, 1000, and unit dose 10 x 10's—Product Number 5362.

for acute schizophrenia*
©McNeil Laboratories, Inc., 1976

Haldol®
(haloperidol)
tablets/concentrate/injection

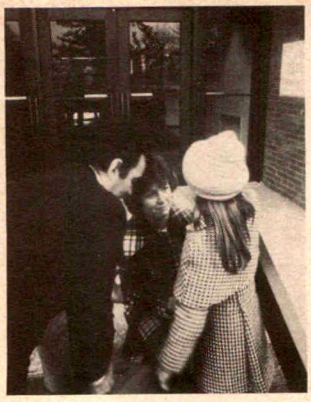
For prompt control with minimal risk of adverse reactions

Highly effective in a wide range of psychotic symptoms,[1-10]
such as hallucinations, delusions, suspiciousness, hostility, mania, psychomotor agitation, etc., in both acute and chronic disorders.

Usually leaves patients more responsive to rehabilitation...[1,2]
better able to care for themselves and take part in therapy sessions.

Helps avoid long-term hospitalization.[1,3-5]
It is often possible to release the patient for treatment as an outpatient after a short confinement. HALDOL haloperidol controls his psychotic symptoms, usually leaving him sufficiently alert to carry on normal functions.

Permits aggressive titration to effective dosage levels,[3,6]
up to 100 mg/day orally, to achieve optimal response when patient is inadequately controlled at lower dosage...to help you promptly control and stabilize new patients.



Common side effects easily controlled.[1,3,6-8]
Although extrapyramidal symptoms (EPS) have been reported frequently, they are usually dose-related and readily controlled with dose adjustment or antiparkinson drugs. EPS often diminish spontaneously with continued use of HALDOL haloperidol.

*Not an actual case history, this situation illustrates the action of HALDOL haloperidol as reported in various clinical studies (available on request).

Reduces risk of several treatment problems.[1,2,6,7,9]
Transient hypotension occurs rarely and severe orthostatic hypotension has not been reported. Marked sedation is rare, although some instances of drowsiness have been reported. In addition, with chronic use, it is unlikely to cause hepatic damage, serious hematologic reactions, photosensitivity reactions and skin rashes...and has minimal effect on renal function.

Please turn page for information relating to Indications, Contraindications, Warnings, Precautions and Adverse Reactions.

Important: Full directions for use should be read before HALDOL haloperidol is administered or prescribed.

Haldol® (haloperidol)

tablets/concentrate/injection

For prompt control of psychotic symptoms with minimal risk of adverse reactions

A Dosage Form for Every Need:

5 tablet strengths for convenience in individualizing dosage: ½ mg., 1 mg., 2 mg., 5 mg. and 10 mg.

A tasteless, odorless, colorless liquid concentrate for better patient acceptability: 2 mg. per ml.

A rapid-acting injection for psychiatric emergencies: 5 mg. per ml., with 1.8 mg. methylparaben and 0.2 mg. propylparaben per ml., and lactic acid for pH adjustment to 3.4±0.2.

Indications: HALDOL haloperidol is indicated for use in the management of manifestations of psychotic disorders.

It is also indicated for the control of tics and vocal utterances of Gilles de la Tourette's syndrome.

Contraindications: HALDOL haloperidol is contraindicated in patients who are severely depressed, comatose, have CNS depression due to alcohol or other centrally-acting depressants, have Parkinson's disease or are hypersensitive to this drug.

Warnings: ***Usage in Pregnancy:*** Safe use of HALDOL haloperidol in pregnancy and lactation has not been established; therefore, its use in pregnancy, in nursing mothers, or in women of childbearing potential requires that the possible benefits of the drug be weighed against the potential hazards. A case of phocomelia in an infant whose mother received haloperidol along with a number of other medications during the first trimester of pregnancy has been reported (a causal relationship was not established in this case). Animals receiving 2 to 20 times the maximum human dose of haloperidol orally and/or parenterally showed increased incidence of resorption, reduced fertility, delayed delivery, dose-related pup mortality (presumably due to lack of maternal care reflecting CNS depression).

Usage in Children: Safety and effectiveness in children have not been established; therefore, this drug is not recommended for use in the pediatric age group.

General: Cases of bronchopneumonia, some fatal, have followed the use of major tranquilizers, including haloperidol. It has been postulated that lethargy and decreased sensation of thirst may lead to dehydration, hemoconcentration and reduced pulmonary ventilation. If these signs and symptoms appear, especially in the elderly, the physician should institute remedial therapy promptly. Although not reported with HALDOL haloperidol, decreased serum cholesterol and/or cutaneous and ocular changes have been reported in patients receiving chemically-related drugs. HALDOL haloperidol may impair the mental and/or physical abilities required for the performance of hazardous tasks such as operating machinery or driving a motor vehicle. The ambulatory patient should be warned accordingly. The use of alcohol should be avoided due to possible additive effects and hypotension.

Precautions: HALDOL haloperidol should be administered cautiously to patients: (1)—with severe cardiovascular disorders, because of the possibility of transient hypotension and/or precipitation of anginal pain. Should hypotension occur and a vasopressor be required, epinephrine should not be used since HALDOL haloperidol may block its vasopressor activity and paradoxical further lowering of blood pressure may occur. (2)—receiving anticonvulsant medication, because HALDOL haloperidol may lower the convulsive threshold. Adequate anticonvulsant therapy should be maintained concomitantly. (3)—with known allergies, or with a history of allergic reactions to drugs. (4)—receiving anticoagulants, since an isolated instance of interference occurred with the effects of one anticoagulant (phenindione).

If concomitant antiparkinson medication is required, it may have to be continued after HALDOL haloperidol is discontinued because of the difference in excretion rates. If both are discontinued simultaneously, extrapyramidal symptoms may occur. Intraocular pressure may increase when anticholinergic drugs, including antiparkinson agents, are administered concomitantly with HALDOL haloperidol. When HALDOL haloperidol is used to control mania in cyclic disorders there may be a rapid mood swing to depression.

Adverse Reactions: ***CNS Effects:*** *Extrapyramidal Reactions*—Neuromuscular (extrapyramidal) reactions have been reported frequently, often during the first few days of treatment. Generally they involved Parkinson-like symptoms which usually were mild to moderately severe and reversible. Other types of neuromuscular reactions (motor restlessness, dystonia, akathisia, hyperreflexia, opisthotonos, oculogyric crises) have been reported far less frequently, but were often more severe. Severe extrapyramidal reactions have been reported at relatively low doses. Generally extrapyramidal symptoms are dose-related since they occur at relatively high doses and disappear or become less severe when the dose is reduced. Administration of antiparkinson drugs may be required for control of such reactions. Persistent extrapyramidal reactions have been reported and the drug may have to be discontinued in such cases. *Persistent Tardive Dyskinesia*—Tardive dyskinesia may appear during long-term therapy or after therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear irreversible. There is no known effective treatment. All antipsychotic agents should be discontinued. The syndrome may be masked by reinstitution of drug, increasing dosage, or switching to a different antipsychotic agent. *Other CNS Effects*—Insomnia, restlessness, anxiety, euphoria, agitation, drowsiness, depression, lethargy, headache, confusion, vertigo, grand mal seizures, and exacerbation of psychotic symptoms including hallucinations. ***Cardiovascular Effects:*** Tachycardia and hypotension. ***Hematologic Effects:*** Reports have appeared of mild and usually transient leukopenia and leukocytosis, minimal decreases in red blood cell counts, anemia, or a tendency toward lymphomonocytosis. Agranulocytosis has rarely been reported and then only in association with other medication. ***Liver Effects:*** Impaired liver function and/or jaundice have been reported, although a causal relationship has not been established. ***Dermatologic Reactions:*** Maculopapular and acneiform skin reactions and isolated cases of photosensitivity and loss of hair. ***Endocrine Disorders:*** Lactation, breast engorgement, mastalgia, menstrual irregularities, gynecomastia, impotence, increased libido, hyperglycemia and hypoglycemia. ***Gastrointestinal Effects:*** Anorexia, constipation, diarrhea, hypersalivation, dyspepsia, nausea and vomiting. ***Autonomic Reactions:*** Dry mouth, blurred vision, urinary retention and diaphoresis. ***Respiratory Effects:*** Laryngospasm, bronchospasm and increased depth of respiration.

Complete dosage information available in insert which accompanies each package (or on request).

The use of the injectable form is intended for the acutely agitated psychotic patient with moderately severe to very severe symptoms.

IMPORTANT: Full directions for use should be read before HALDOL haloperidol is administered or prescribed. 9/

McNEIL McNeil Laboratories, Inc., Fort Washington, Pa. 19034

Indication: For relief of mental depression. **Contraindications:** Do not use MAO inhibitors concomitantly or within 2 weeks of the use of this drug. Hyperpyretic crises or severe convulsive seizures may occur with such combinations; potentiation of adverse reactions can be serious or even fatal. When substituting Pertofrane (desipramine HCl) in patients receiving an MAO inhibitor, allow an interval of at least 14 days. Initial dosage in such patients should be low and increases should be gradual and cautiously prescribed. The drug is contraindicated following recent myocardial infarction and in patients with a known hypersensitivity to tricyclic antidepressants. **Warnings:** Activation of psychosis may occasionally be observed in schizophrenic patients. Due to atropine-like effects and sympathomimetic potentiation, use only with the greatest care in patients with narrow-angle glaucoma or urethral or ureteral spasm. Do not use in patients with the following conditions unless the need outweighs the risk: severe coronary heart disease with EKG abnormalities, progressive heart failure, angina pectoris, paroxysmal tachycardia and active seizure disorder (may lower seizure threshold). This drug may block the action of the antihypertensive, guanethidine, and related adrenergic neuron-blocking agents. Hypertensive episodes have been observed during surgery. The concurrent use of other central nervous system drugs or alcohol may potentiate adverse effects. Since many such drugs may be used during surgery, desipramine should be discontinued prior to elective procedures. Caution patients on the possibility of impaired ability to operate a motor vehicle or dangerous machinery. Do not use in women who are or may become pregnant, or in children under 12 years of age, unless the clinical situation warrants the potential risk. Because of increased sensitivity to the drug, use lower than normal dosage in adolescent and geriatric patients. **Precautions:** Potentially suicidal patients require careful supervision and protective measures during therapy. Prescriptions should be limited to small quantities. Discontinuation of the drug may be necessary in the presence of increased agitation and anxiety shifting to hypomanic or manic excitement. Atropine-like effects may be more pronounced (e.g. paralytic ileus) in susceptible patients and in those receiving anticholinergic drugs (including antiparkinsonism agents). Prescribe cautiously in hyperthyroid patients and in those receiving thyroid medications; transient cardiac arrhythmias have occurred in rare instances. Periodic blood and liver studies should supplement careful clinical observations in all patients undergoing extended courses of therapy. **Adverse Reactions:** The following have been reported: *Nervous System:* dizziness, drowsiness, insomnia, headache, disturbed visual accommodation, tremor, unsteadiness, tinnitus, paresthesias, changes in EEG patterns, epileptiform seizures, mild extrapyramidal activity, falling and neuromuscular incoordination. A confusional state (with such symptoms as hallucinations and disorientation), particularly in older patients and at higher dosage, may require discontinuation of the drug. *Gastrointestinal Tract:* anorexia, dryness of the mouth, nausea, epigastric distress, constipation and diarrhea. *Skin:* skin rashes (including photosensitization), perspiration and flushing sensations. *Liver:* rare cases of transient jaundice (apparently of an obstructive nature) and liver damage. If jaundice or abnormalities in liver function tests occur, discontinue the drug and investigate. *Blood Elements:* bone-marrow depression, agranulocytosis, thrombocytopenia and purpura. If these occur, discontinue the drug. Transient eosinophilia has been observed. *Cardiovascular System:* orthostatic hypotension and tachycardia. Carefully supervise patients requiring concomitant vasodilating therapy, particularly during initial phases. *Genitourinary System:* urinary frequency or retention and impotence. *Endocrine System:* occasional hormonal effects, including gynecomastia, galactorrhea and breast enlargement, and decreased libido and estrogenic effect. *Sensitivity:* urticaria and rare instances of drug fever and cross-sensitivity with imipramine. **Dosage:** All patients except geriatric and adolescent: 50 mg. t.i.d. (150 mg. daily). Dosage may be increased up to 200 mg. daily. Geriatric and adolescent patients should usually be started with lower dosage (25 to 50 mg. daily) and may not tolerate higher doses. Dosage may be increased up to 100 mg. daily. Lower maintenance dosages should be continued for at least 2 months after obtaining a satisfactory response. Mild anxiety and agitation which may accompany depression usually remit as the depression responds. Occasionally, however, a sedative or tranquilizer may be indicated. **How Supplied:** 25 mg. capsules (pink), bottles of 100 and 1000. Also, 50 mg. capsules (maroon and pink), bottles of 100 and 1000.

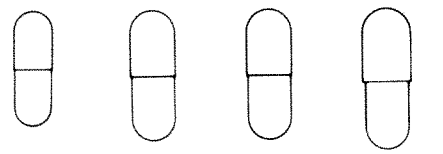
Unsurpassed effectiveness
among tricyclics in relieving symptoms
of depression.
Before prescribing Tofranil-PM, please review the prescribing
information summarized on the back of this page.

Geigy

Tofranil-PM®
imipramine **pamoate**

As symptoms are relieved, mood and motivation may be markedly improved.



Patients are usually alert and capable of functioning at more normal levels of behavior.

Good results are usually seen at the starting dose of one 75-mg capsule h.s.

For many patients, dosage can be safely increased to 150 mg daily.

Because sedation may occur, caution patients against driving or operating dangerous machinery.

Before prescribing Tofranil-PM, please review the prescribing information summarized on this page.

75 mg 100 mg 125 mg 150 mg

Each capsule contains imipramine pamoate equivalent to 75, 100, 125 or 150 mg of imipramine hydrochloride.

Tofranil-PM®
brand of imipramine pamoate

Indications: For the relief of symptoms of depression. Endogenous depression is more likely to be alleviated than other depressive states.

Contraindications: The concomitant use of monoamine oxidase inhibiting compounds is contraindicated. Hyperpyretic crises or severe convulsive seizures may occur in patients receiving such combinations. The potentiation of adverse effects can be serious, or even fatal. When it is desired to substitute Tofranil-PM, brand of imipramine pamoate, in patients receiving a monoamine oxidase inhibitor, as long an interval should elapse as the clinical situation will allow, with a minimum of 14 days. Initial dosage should be low and increases should be gradual and cautiously prescribed. The drug is contraindicated during the acute recovery period after a myocardial infarction. Patients with a known hypersensitivity to this compound should not be given the drug. The possibility of cross-sensitivity to other dibenzazepine compounds should be kept in mind.

Warnings: *Usage in Pregnancy:* Safe use of imipramine during pregnancy and lactation has not been established; therefore, in administering the drug to pregnant patients, nursing mothers, or women of childbearing potential, the potential benefits must be weighed against the possible hazards. Animal reproduction studies have yielded inconclusive results. There have been clinical reports of congenital malformation associated with the use of this drug, but a causal relationship has not been confirmed.

Extreme caution should be used when this drug is given to:

—patients with cardiovascular disease because of the possibility of conduction defects, arrhythmias, myocardial infarction, strokes and tachycardia;
—patients with increased intraocular pressure, history of urinary retention, or history of narrow-angle glaucoma because of the drug's anticholinergic properties;
—hyperthyroid patients or those on thyroid medication because of the possibility of cardiovascular toxicity;
—patients with a history of seizure disorder because this drug has been shown to lower the seizure threshold;
—patients receiving guanethidine or similar agents since imipramine may block the pharmacologic effects of these drugs.

Since imipramine may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as operating an automobile or machinery, the patient should be cautioned accordingly.

Usage in Children: Tofranil-PM, brand of imipramine pamoate, should not be used in children of any age because of the increased potential for acute overdosage due to the high unit potency (75 mg., 100 mg., 125 mg. and 150 mg.). Each capsule contains imipramine pamoate equivalent to 75 mg., 100 mg., 125 mg. or 150 mg. imipramine hydrochloride.

Precautions: It should be kept in mind that the possibility of suicide in seriously depressed patients is inherent in the illness and may persist until significant remission occurs. Such patients should be carefully supervised during the early phase of treatment with Tofranil-PM, brand of imipramine pamoate, and may require hospitalization. Prescriptions should be written for the smallest amount feasible.

Hypomanic or manic episodes may occur, particularly in patients with cyclic disorders. Such reactions may necessitate discontinuation of the drug. If needed, Tofranil-PM, brand of imipramine pamoate, may be resumed in lower dosage when these episodes are relieved. Administration of a tranquilizer may be useful in controlling such episodes.

Prior to elective surgery, imipramine should be discontinued for as long as the clinical situation will allow.

An activation of the psychosis may occasionally be observed in schizophrenic patients and may require reduction of dosage and the addition of a phenothiazine.

In occasional susceptible patients or in those receiving anticholinergic drugs (including antiparkinsonism agents) in addition, the atropine-like effects may become more pronounced (e.g., paralytic ileus). Close supervision and careful adjustment of dosage is required when this drug is administered concomitantly with anticholinergic or sympathomimetic drugs.

Avoid the use of preparations, such as decongestants and local anesthetics, which contain any sympathomimetic amine (e.g., adrenalin, noradrenalin), since it has been reported that tricyclic antidepressants can potentiate the effects of catecholamines.

Patients should be warned that the concomitant use of alcoholic beverages may be associated with exaggerated effects.

Both elevation and lowering of blood sugar levels have been reported.

Concurrent administration of imipramine with electroshock therapy may increase the hazards; such treatment should be limited to those patients for whom it is essential, since there is limited clinical experience.

Adverse Reactions: Note: Although the listing which follows includes a few adverse reactions which have not been reported with this specific drug, the pharmacological similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when imipramine is administered.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke, falls.

Psychiatric: Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurological: Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alterations in EEG patterns; tinnitus.

Anticholinergic: Dry mouth, and, rarely, associated sublingual adenitis; blurred vision, disturbances of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

Allergic: Skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight); edema (general or of face and tongue); drug fever; cross-sensitivity with desipramine.

Hematologic: Bone marrow depression including agranulocytosis; eosinophilia; purpura; thrombocytopenia. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathological neutrophil depression.

Gastrointestinal: Nausea and vomiting, anorexia, epigastric distress, diarrhea, peculiar taste, stomatitis, abdominal cramps, black tongue.

Endocrine: Gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood sugar levels.

Other: Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency; drowsiness, dizziness, weakness and fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: Though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache and malaise.

Dosage and Administration: In adult outpatients, therapy should be initiated on a once-a-day basis with 75 mg./day. This may be increased to 150 mg./day which is the dose level which usually obtains optimum response. If necessary, dosage may be increased to 200 mg./day. Dosage should be modified as necessary by clinical response and any evidence of intolerance. Daily dosage may be given at bedtime, or in some patients in divided daily doses.

Hospitalized patients should be started on a once-a-day basis with 100-150 mg./day and may be increased to 200 mg./day. Dosage should be increased to 250-300 mg./day if there is no response after two weeks.

Following remission, maintenance medication may be required for a longer period of time at the lowest dose that will maintain remission. The usual adult maintenance dosage is 75-150 mg./day on a once-a-day basis, preferably at bedtime.

In adolescent and geriatric patients, capsules of Tofranil-PM, brand of imipramine pamoate, may be used when total daily dosage is established at 75 mg. or higher. It is generally unnecessary to exceed 100 mg./day in these patients. This dosage may be given once a day at bedtime or, if needed, in divided daily doses.

How Supplied: Tofranil-PM, brand of imipramine pamoate: Capsules of 75, 100, 125 and 150 mg. (Each capsule contains imipramine pamoate equivalent to 75, 100, 125 or 150 mg. of imipramine hydrochloride.)

Just Published . . .

The Rape Victim

by Elaine Hilberman, M.D.

Mythologies about rape are legion. However, in recent years behavioral scientists have accumulated a body of information about rape and about an unfolding series of reactions experienced by the victim after rape. The aim of this concise, tightly reasoned book is to summarize what is now known about the needs and experiences of the victim and her family, and to provide a framework in which the clinician can more knowledgeably supply assistance and support. This document, published by the American Psychiatric Association, is the result of a project of the Association's Committee on Women.

Pointing out that the profound impact of rape stress is best understood in the context of rape as "a crime against the person and not the hymen," Dr. Hilberman sees rape as the ultimate violation of the self short of homicide, as an act of violence and humiliation in which not only is the victim's very existence threatened, and her inner and most private space invaded, but her autonomy and control are totally demolished. Dr. Hilberman shows that if and when the victim reports the crime, she is confronted with a complex series of yet additional stresses growing out of her contact with the hospital, police, courts, media and community opinion. Additionally, her crisis differs from other crises in that her usual social support system is likely to be disrupted. Her immediate needs are for empathy and safety, and a sense of control over what is happening in her dealings with the several agencies. Dr. Hilberman shows that in the absence of sensitivity to these needs, the experience of reporting becomes another assault.

This book presents a professional, sobering, and balanced picture of the problems of the rape victim and details what the clinician must know—about local hospital policy, criminal justice procedure, rape statutes, and community attitudes and services—in order to be able to treat victims with an understanding of the larger context in which rape occurs.

ELAINE HILBERMAN, M.D., *is in the Department of Psychiatry at the University of North Carolina School of Medicine.*

In treating the schizophrenic, there's something different about

MOBAN®
(molindone HCl)

acts on the RAS with low incidenc of adverse effects

EEG studies show that MOBAN® exerts its effect on the ascending reticular activating system. This often helps to encourage increased social participation, receptivity and communication in schizophrenic patients.

Artist's representation of the reticular activating system, with neuronal activity passing on to cortical and subcortical

- generally minimizes drowsiness to help produce improved functioning
  1) to hasten the discharge of hospitalized patients
  2) to keep ambulatory patients at home or on the job

- tranquilizes without muscle relaxant or incoordinating effect

- acts to alleviate target symptoms or reduce their severity
  1) in acute patients, some symptomatic improvement evident in a few days
  2) in chronic patients, symptomatic improvement may not be evident until 2-4 weeks
  3) maximum benefits attained by end of third month (continued maintenance therapy as required)

SOCIAL ADJUSTMENT PROFILE CHART

of 66 hospitalized schizophrenic patients treated with MOBAN® (molindone HCl) for 1 year or more*

Adjustment	Percent
To live on open ward	91%
To function with privileges	89%
To hold hospital job	85%
To leave hospital	70%
To maintain home	33%
To hold employment	32%

*Data on file, Endo Laboratories

How to use MOBAN® (molindone HCl)

a wide range of dosage strengths available in **Tablets:**

- Titrate for 1) therapeutic response and 2) minimal effective maintenance dose.
- Use lower doses for the elderly and debilitated.

NOTE: Transient drowsiness may occur during the first 1-2 weeks.

Whenever your schizophrenic patient may benefit from less sedation

DUPONT

MOBAN® (molindone HCl)

a dihydroindolone chemically distinct from phenothiazines, thioxanthenes, butyrophenones

DESCRIPTION MOBAN® (molindone hydrochloride) is a dihydroindolone compound which is not structurally related to the phenothiazines, the butyrophenones or the thioxanthenes.

MOBAN® is 3-ethyl-6, 7-dihydro-2-methyl-5-(morpholinomethyl) indol-4 (5H)-one hydrochloride. It is a white crystalline powder, freely soluble in water and alcohol and has a molecular weight of 312.67.

MOLINDONE HYDROCHLORIDE

ACTIONS MOBAN® (molindone hydrochloride) has a pharmacological profile in laboratory animals which predominantly resembles that of major tranquilizers causing reduction of spontaneous locomotion and aggressiveness, suppression of a conditional response and antagonism of the bizarre stereotyped behavior and hyperactivity induced by amphetamines. In addition, MOBAN® antagonizes the depression caused by the tranquilizing agent tetrabenazine.

In human clinical studies tranquilization is achieved in the absence of muscle relaxing or incoordinating effects. Based on EEG studies, MOBAN® exerts its effect on the ascending reticular activating system.

Human metabolic studies show MOBAN® (molindone hydrochloride) to be rapidly absorbed and metabolized when given orally. Unmetabolized drug reached a peak blood level at 1.5 hours. Pharmacological effect from a single oral dose persists for 24-36 hours. There are 36 recognized metabolites with less than 2-3% unmetabolized MOBAN® being excreted in urine and feces.

INDICATIONS MOBAN® (molindone hydrochloride) is indicated in the management of the manifestations of schizophrenia.

CONTRAINDICATIONS MOBAN® (molindone hydrochloride) is contraindicated in severe central nervous system depression (alcohol, barbiturates, narcotics, etc.) or comatose states, and in patients with known hypersensitivity to the drug.

WARNINGS Usage in Pregnancy: Studies in the pregnant patient have not been carried out. Reproduction studies have been performed in the following animals:

Pregnant Rats oral dose—	20 mg/kg/day—2 weeks
no adverse effect	
	40 mg/kg/day—2 weeks
no adverse effect	
Pregnant Mice oral dose—	20 mg/kg/day—9 days
slight increase resorptions	
	40 mg/kg/day—9 days
slight increase resorptions	
Pregnant Rabbits oral dose—	5 mg/kg/day—12 days
no adverse effect	
	10 mg/kg/day—12 days
no adverse effect	
	20 mg/kg/day—12 days
no adverse effect	

Animal reproductive studies have not demonstrated a teratogenic potential. The anticipated benefits must be weighed against the unknown risks to the fetus if used in pregnant patients.

Nursing Mothers: Data are not available on the content of MOBAN® (molindone hydrochloride) in the milk of nursing mothers.

Usage in Children: Use of MOBAN® (molindone hydrochloride) in children below the age of twelve years is not recommended because safe and effective conditions for its usage have not been established.

PRECAUTIONS Some patients receiving MOBAN® (molindone hydrochloride) may note drowsiness initially and they should be advised against activities requiring mental alertness until their response to the drug has been established.

Increased activity has been noted in patients receiving MOBAN®. Caution should be exercised where increased activity may be harmful.

MOBAN® does not lower the seizure threshold in experimental animals to the degree noted with more sedating antipsychotic drugs. However, convulsive seizures have been reported in a few instances.

The physician should be aware that this tablet preparation contains calcium sulfate as an excipient and that calcium ions may interfere with the absorption of preparations containing phenytoin sodium and tetracyclines.

MOBAN® has an antiemetic effect in animals. A similar effect may occur in humans and may obscure signs of intestinal obstruction or brain tumor.

ADVERSE REACTIONS CNS EFFECTS The most frequently occurring effect is initial drowsiness that generally subsides with continued usage of the drug or lowering of the dose.

Noted less frequently were depression, hyperactivity and euphoria.

Neurological

Extrapyramidal Reactions

Extrapyramidal reactions noted below may occur in susceptible individuals and are usually reversible with appropriate management.

Akathisia

Motor restlessness may occur early.

Parkinson Syndrome

Akinesia, characterized by rigidity, immobility and reduction of voluntary movements and tremor, have been observed. Occurrence is less frequent than akathisia.

Dystonic Syndrome

Prolonged abnormal contractions of muscle groups occur infrequently. These symptoms may be managed by the addition of a synthetic antiparkinson agent (other than L-dopa), small doses of sedative drugs, and/or reduction in dosage.

Autonomic Nervous System

Occasionally blurring of vision, tachycardia, nausea, dry mouth and salivation have been reported. Urinary retention and constipation may occur particularly if anticholinergic drugs are used to treat extrapyramidal symptoms.

Hematological

There have been rare reports of leucopenia and leucocytosis. If such reactions occur, treatment with MOBAN® may continue if clinical symptoms are absent. Alterations of blood glucose, liver function tests, B.U.N., and red blood cells have not been considered clinically significant.

Metabolic and Endocrine Effects

Alteration of thyroid function has not been significant. Amenorrhea has been reported infrequently. Resumption of menses in previously amenorrheic women has been reported. Initially heavy menses may occur. Lactation associated with MOBAN® therapy has not been reported. Increase in libido has been noted in some patients. Impotence has not been reported. Although both weight gain and weight loss have been in the direction of normal or ideal weight, excessive weight gain has not occurred with MOBAN®.

Cardiovascular

Rare, transient, non-specific T wave changes have been reported on E.K.G. Association with a clinical syndrome has not been established. Rarely has significant hypotension been reported.

Ophthalmological

Lens opacities and pigmentary retinopathy have not been reported where patients have received MOBAN® (molindone hydrochloride). In some patients, phenothiazine induced lenticular opacities have resolved following discontinuation of the phenothiazine while continuing therapy with MOBAN®.

Skin

Early, non-specific skin rash, probably of allergic origin, has occasionally been reported. Skin pigmentation has not been seen with MOBAN® usage alone.

MOBAN® (molindone hydrochloride) has certain pharmacological similarities to other antipsychotic agents. Because adverse reactions are often extensions of the pharmacological activity of a drug, all of the known pharmacological effects associated with other antipsychotic drugs should be kept in mind when MOBAN® is used. Upon abrupt withdrawal after prolonged high dosage an abstinence syndrome has not been noted.

Tardive Dyskinesia

Although not reported with MOBAN® (molindone hydrochloride) late appearing dyskinesias have been associated with certain antipsychotic agents.

Tardive dyskinesia associated with other agents has appeared in some patients on long-term therapy and has also appeared after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). There may be involuntary movements of extremities.

There is no known effective treatment of tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time the syndrome may not develop.

DOSAGE AND ADMINISTRATION Initial and maintenance doses of MOBAN® (molindone hydrochloride) should be individualized, and the minimal effective dose should be employed. Elderly and debilitated patients should be started on lower dosage.

DOSAGE SCHEDULE, BASED ON SEVERITY OF SYMPTOMATOLOGY

1. Mild—5 mg three or four times a day; an increase to 15 mg three or four times a day may be required.
2. Moderate—10 mg three or four times a day; an increase to 25 mg three or four times a day may be required.
3. Severe—daily dosage as high as 225 mg may be required.

DRUG INTERACTIONS Potentiation of drugs administered concurrently with MOBAN® (molindone hydrochloride) has not been reported. Additionally, animal studies have not shown increased toxicity when MOBAN® is given concurrently with representative members of three classes of drugs (i.e., barbiturates, chloral hydrate and antiparkinson drugs).

MANAGEMENT OF OVERDOSAGE Symptomatic, supportive therapy should be the rule.

Gastric lavage is indicated for the reduction of absorption of MOBAN® (molindone hydrochloride) which is freely soluble in water.

Since the adsorption of MOBAN® (molindone hydrochloride) by activated charcoal has not been determined, the use of this antidote must be considered of theoretical value.

Emesis in a comatose patient is contraindicated. Additionally, while the emetic effect of apomorphine is blocked by MOBAN® in animals, this blocking effect has not been determined in humans.

A significant increase in the rate of removal of unmetabolized MOBAN® from the body by forced diuresis, peritoneal or renal dialysis would not be expected. (Only 2% of a single ingested dose of MOBAN® is excreted unmetabolized in the urine.)

However, poor response of the patient may justify use of these procedures. While the use of laxatives or enemas might be based on general principles, the amount of unmetabolized MOBAN® in feces is less than 1%. Extrapyramidal symptoms have responded to the use of diphenhydramine (Benadryl*) and the synthetic anticholinergic antiparkinson agents (i.e., Artane*, Cogentin*, Akineton*).

HOW SUPPLIED As tablets in bottles of 100 and 1000 with potencies and colors as follows: 5 mg orange, 10 mg lavender, 25 mg light green.

*Benadryl—Trademark, Parke Davis and Co.
*Artane—Trademark, Lederle Laboratories
*Cogentin—Trademark, Merck Sharp & Dohme
*Akineton—Trademark, Knoll Pharmaceutical Co.

In the hospitalized patient...
For Brief Summary, please see following page.
SANDOZ

ANTIPSYCHOTIC EFFICACY... INFREQUENT EXTRAPYRAMIDAL SYMPTOMS

Antipsychotic medication should not interfere with the patient's ability to participate in your total therapeutic program. That is why Mellaril (thioridazine) is an excellent choice. It is highly effective, and although extrapyramidal symptoms are characteristic of this class of drug, with Mellaril (thioridazine) extrapyramidal stimulation—notably pseudoparkinsonism—is infrequent. Adding an antiparkinsonian agent—which can cause its own side effects—can usually be avoided.

Mellaril (thioridazine) is not habituating and usually does not cause euphoria or undue sedation. (But, warn patients about undertaking activities requiring complete mental alertness.) And Mellaril (thioridazine) is contraindicated in patients with severe hypotensive or hypertensive heart disease.

MELLARIL® (THIORIDAZINE)

TABLETS: 50 mg, 100 mg, 150 mg, and 200 mg thioridazine HCl, U.S.P.

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg. should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling.

The following reactions have occurred with phenothiazines and should be considered: *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

THE AMERICAN JOURNAL OF PSYCHIATRY

A Bicentennial Address: Benjamin Rush and Those Who Came After Him

BY FRANCIS J. BRACELAND, M.D.

In this Bicentennial year, the author takes a look at the early days of American psychiatry, focusing on some of the great men who helped to form the discipline. These men have much to teach us in a time when the field is divided within and faces a crisis of public confidence without. We can learn much from men like Benjamin Rush, who although they were actively involved in the social movements of their day, remained always the physician. Dr. Braceland suggests that it is time for psychiatry to move back into the mainstream of medicine, retaining, of course, mastery of psychotherapeutic techniques and knowledge of psychodynamics. This move can best be accomplished by employing the principle of complementarity, the art of encompassing different approaches to problems and utilizing the essentials of each to arrive at workable solutions.

How does one present a subject with so many facets as this one? A lengthy dissertation on the lives of Benjamin Rush and his successors, repeating what one could read in history books, would be deadly and would risk what Longfellow said of past history. He called it a puppet show in which a little man comes out and blows a trumpet and goes in again. You look for something new and lo, another little man comes out and blows a trumpet and it is all over. That, of course, we cannot risk.

It was decided finally to view the subject from the editor's perch, a generally pleasant place, elevated just enough to fan the ego of the occupant and encourage him to write about what has happened and what seems to be happening without being held too strictly to account.

Cervantes believed that history is the depository of great actions, the witness of what is past, the example and instructor of the present, and the monitor of the future. Carlyle saw the history of the world as the biography of great men and believed that no great man ever lived in vain. With this authority, one is heartened about taking a backward glance at psychiatry's origins in this Bicentennial year. In this paper I will briefly describe the contributions of some of the men who helped to form our discipline in an attempt to show how great men make history and the times make men great.

Earl Bond (1) warned that defining greatness is a hopeless task, for a great man is multifaceted and his greatness is partly his own and partly the product of unusual opportunities or environment. He thought that because great men have a harder time managing themselves than do average people, one should look for a common denominator not in the triumphs but in the troubles of great men. This is appealing to us, for we know that if anyone can get into trouble easily, it is a psychiatrist. However, we cannot award anyone the palm of greatness simply for having trouble, so we will only call him great who has done great things, taught others how they might be done, or described them with suitable majesty when they were done.

Thus circumscribed, I will report only on those of our ancestors who have something to teach us in our present situation. Reluctantly, I must perforce neglect many wonderful men who helped form our discipline.

Revised version of a special lecture written at the invitation of the Program Committee and presented at the 129th annual meeting of the American Psychiatric Association, Miami Beach, Fla., May 10–14, 1976.

Dr. Braceland is Editor of the *Journal* and Senior Consultant, Institute of Living, 200 Retreat Ave., Hartford, Conn. 06106. He is also Past President of the American Psychiatric Association (1956–1957) and Emeritus Professor of Clinical Psychiatry, Yale University.

THE FATHER OF AMERICAN PSYCHIATRY

There is no doubt that Benjamin Rush had troubles. In fact, he was usually in trouble, and history has had trouble placing him in proper perspective. He is known as the father of American psychiatry, although that paternal title has been disputed by some. Thomas Jefferson made known his disagreement with his friend Rush's treatment methods. James T. Flexner (2) went so far as to ask, "Was he Saint or Scourge?" William Bean, one of our contemporaries, castigated Rush for his foolish concept of fever. All of these men admitted that Rush's motives were pure and sincere, but Bean thought Rush's beliefs were one more example of man's innate capacity to fool himself.

Adolf Meyer (3) examined Rush's background thoroughly and decided he was an excellent teacher of medicine who urged his students to know man as an indivisible unit. Rush described the mind of man as the first production of creative power and wisdom in the world, and he believed that although all else will pass away, the mind of man will live forever.

Norman Dain (4), an excellent historian, saw Rush with all his faults as a transitional figure in the history of psychiatry, a man who broke with traditional belief—who insisted that mental illness be freed from moral stigma, that the mentally ill be treated with kindness, that their care be under the supervision of physicians, and that religious melancholia be treated with medicine rather than moralizing.

Rush wrote a letter to the managers of the Pennsylvania Hospital that is a classic and should be required reading for psychiatrists. The last paragraph was pathetic. He asked members of the Board to recall that he had advocated methods for the improvement of the conditions and comfort of the mentally ill under their care "long before it pleased God to interest me in their adoption by rendering one of my family an object of them" (5, p. 1067). His reference was to a brilliant son who killed a friend in a duel, became psychotic, and died on the wards his father had organized.

Rush was involved in all of the great reform movements of the day—abolitionism, prison reform, better education for women, etc. A signer of the Declaration of Independence, he also served as a member of the Continental Congress and as a physician in the Continental Army. He was the foremost physician of his day, and his prestige lasted over several generations. "European medical men called him the 'Sydenham of America' or the 'American Hippocrates' " (4, p. 22). Withal, the poor were his main concern, and he visited them in their huts and hovels. His watchword, "Take care of them and I will repay thee," became the motto of the Pennsylvania Hospital.

Rush's book *Medical Inquiries and Observations Upon the Diseases of the Mind* (6) was the first psychiatric text by an American and went through five editions between 1812 and 1835. What can be learned from this active, productive life other than that he consistently gave of himself? Perhaps the most important lesson is that although Rush was at the forefront of all the great social movements of the day, he remained always the physician, an important quality that is in danger of being forgotten by some of us today.

ELI TODD AND THE SPREAD OF MORAL TREATMENT

In 1812, Dr. Eli Todd, a young physician in Farmington, Conn., read Rush's *Medical Inquiries* with interest. Already at odds with the distinguished Philadelphian on certain basic points of medical practice, he then found himself in disagreement with Rush in regard to the treatment of the mentally ill. Todd was a gentle, quiet person (rather the antithesis of Rush) who understandably espoused the use of moral treatment. This approach involved gaining the patient's confidence, treating him with unfailing courtesy, and encouraging every healthy tendency within him. We can detect in this treatment influences that are today subsumed under the term "rehabilitation." None of it was scientifically expressed or scientifically formulated—it was treatment exercised purposefully day in and day out, and under this heading a small but advanced therapeutic community was brought into being.

Todd realized the need for follow-up after the patient left the institution. He also recognized the importance of work, as is evidenced in this paragraph from a letter he wrote to the family of a patient:

> I improve a moment on the eve of your son's departure . . . to express the pleasure I feel, in being able to restore him to his anxious friends, nearly, if not quite, as he was in his best days. . . . I cannot too strenuously urge the advantage, and even necessity, of his being immediately engaged in some regular employment . . . which shall hold out the promise of a moderate but fair compensation to his industry and prudence.[1]

Todd was the founder and first superintendent of the Hartford Retreat, now known as the Institute of Living. It was primarily through Todd's example that moral treatment spread throughout all of New England. He wrote little and paid only slight attention to theory. His greatest contributions were his example as a physician, his excellent hospital, his dedicated care of his patients, and his inspiration of a number of men who carried his methods and ideals with them to other New England hospitals. Among these men were several who became great in their own right: Samuel Woodward, the distinguished head of Worcester State Hospital; the brilliant and tragic Thomas G. Lee, who became the head of McLean Hospital; William Rockwell, the first superintendent of the Brattleboro Retreat; and Amariah Brigham, who succeeded Todd at the Hartford Retreat. These men were Todd's con-

[1]This letter is now in the Archives of the Institute of Living.

siderable legacy to American psychiatry, but he never quite received the credit he deserved.

A number of important New England hospitals were modeled after the Hartford Retreat, and the whole region benefited immeasurably from Todd's work and that of his pupils. Todd thus fulfills our criteria for greatness and brings to mind Chesterton's statement, "There is a [type of] great man who makes every man feel small, but a real great man is the man who makes every other man feel great."

Rufus Wyman of McLean Hospital should probably be mentioned with Todd, for the two men thought alike and installed similar systems in their hospitals. One never hears very much of Wyman, a phenomenologist, because he suffered from a condition not common in psychiatrists—he was modest and retiring and avoided the limelight. Although one heard little of his hospital or his work, both were of high calibre. Amariah Brigham extolled him as a man of ability, integrity, and devotion whose one fault was his excessive modesty.

OUR FIRST EDITOR

Amariah Brigham, one of Todd's better known disciples, was a brilliant, quiet, cultured cosmopolite. He typifies for us the axiom that "to be great is often to be misunderstood, and at times even to be persecuted because of misunderstanding." Brigham wrote one book, *Remarks on the Influence of Mental Cultivation and Mental Excitement Upon Health* (7), before he started his psychiatric career. Albert Deutsch called this book "By all odds the most popular of American works on psychosomatic medicine in the first half of the nineteenth century" and said it was a pioneer work in the area of mental hygiene known as child guidance (8, p. 327). The book's object was to awaken public attention to the need to modify educational methods, giving more attention to bodily health and less to cultivation of the mind in early life. "Early mental excitement," Brigham said, "will serve only to bring forth beautiful but premature flowers, which are destined soon to wither away without producing fruit" (7, p. 98).

Brigham was a fine man who did not hesitate to take textbooks with him when called in consultation. He wanted to know everything about the case. He was not above carrying a fishing pole along also, in case some inviting stream should beckon. Although he was deeply religious, Brigham, who became superintendent of the Hartford Retreat in 1840, warned of the dangers of the high emotional pitch being raised in the revival meetings of the day in his volume *Observations on the Influence of Religion Upon the Health and Welfare of Mankind* (9). In this work he quoted reports from religious papers of conversions at such meetings. Norman Dain notes that

> Fits and seizures were common among the audiences at revival meetings. In some cases the affected persons were clearly mentally unstable, if not insane, but credulous laymen as well as clergymen were diverted from recognizing them as such. In one example cited by Brigham, a religious paper reported the conversion of a man and woman through the Holy Spirit: the man fell to the ground, cold and still, as in death, while the woman "suddenly turned into a marble-like, cold and motionless statue; her eyes were fixed in her head, and many thought her to be dying . . . ." To Brigham these were obvious cases of "catalepsy," a form of mental illness. Even outside the hysterical atmosphere of the meetings, pathological behavior was often confused with religious fervor. Spiritualism, which was in vogue before the Civil war, produced similar effects. (4, pp. 189–190)

Brigham was sharply attacked by the clergy and the popular press as a materialist and a phrenologist. One critic in the *Christian Spectator*, a religious paper, noted that "the antiseptic quiet Brigham advocated would drive the healthiest person insane" and repeated the rumor that one person had had to be sent to a mental hospital as a result of reading Brigham's book (4, p. 191). Brigham felt it necessary to defend himself as a believer in God and a religious man. Although the situation in Hartford eventually quieted down, the feeling lingered on, and Brigham, who had expected to spend the rest of his life at the Hartford Retreat, accepted when he was asked to be the first superintendent of the New York State Lunatic Asylum in Utica.

In Utica, his restless energy again asserted itself, and in July 1844 he founded the *American Journal of Insanity*, which you know today as the *American Journal of Psychiatry*, and paid for it out of his own pocket. The *Journal* was well done and served to keep the practitioners of the new, loosely organized specialty in touch with one another. It was also undoubtedly one of the major factors leading to the formation of the Association of Medical Superintendents of American Institutions for the Insane, now the American Psychiatric Association. Brigham was one of the Association's 13 founders. Great man that he was, he possessed qualities that enabled him to meet and make great occasions.

AN ECLECTIC REFORMER

Samuel B. Woodward, another distinguished physician especially close to Eli Todd, was the first superintendent of the Worcester State Hospital (then the State Lunatic Hospital at Worcester), a position for which Todd had recommended him. His achievements at Worcester were so outstanding that in 1844 his colleagues elected him first President of the new Association of Medical Superintendents. He was imbued with an ardent social consciousness and believed that man has a religious obligation to better society and to help his fellow man.

As Grob notes (10), Woodward's medical remedies grew out of his empirical, commonsense approach. Unfortunately, his claims concerning the curability of in-

sanity received widespread attention and criticism in the 1830s and 1840s and set up what Deutsch called the "cult of curability."

In 1876, Pliny Earle reexamined Woodward's statistics (among others) in his volume *The Curability of Insanity: A Series of Studies* (11). He noted the drop in the cure rate at Worcester State Hospital over a 5-year period and pointed out that Woodward's statistics were inflated because he reported several recoveries for individuals suffering from recurrent disorders. However, a reexamination of Woodward's statistics years later proved that he was actually not too far wrong (12).

His annual reports, distributed in editions running as high as 3,000–4,000, served to initiate a crusade that would later be led by Dorothea Dix and other reformers. According to Pliny Earle, Woodward and Dorothea Dix gave to the profession and the world more than any other two people. The mentally ill of our country are indebted to these two individuals for awakening public interest in their behalf.

Two aspects of Woodward's beliefs merit our particular attention. The first is his eclecticism: Woodward borrowed from all schools of thought in his treatment approach. Eclecticism, a dirty word in the 1930s and 1940s, has come back into its own and is once again respectable. The second aspect is his belief that there was nothing worse for patients than inactivity of body and mind. Woodward was an ardent advocate of occupational therapy. We now read reports in the popular press of complaints of patients in state hospitals who used to make pin money doing simple uncomplicated chores but are now denied this opportunity because the law requires that they be paid the minimum wage, which few hospitals can do. So these patients sit idle and go without funds for simple necessities. I know, of course, that there were abuses of the system, but I believe they could be controlled today. "Progress" has overtaken us, however, and many patients who would like to work must remain idle.

THE GENTLE QUAKER

Thomas Story Kirkbride literally commands our attention, not only because of the excellence of his facility, The Pennsylvania Hospital, but also because his name is attached to the planning of numerous other institutions. His book, *On the Construction, Organization, and General Arrangements of Hospitals for the Insane* (13), was the standard text on this subject during the nineteenth century.

The year 1844 changed Kirkbride's life, for it was then that he joined with 12 men who carried on work similar to that which absorbed him. He had this group to dinner at his home on the hospital grounds the night before they were to meet at the Jones Hotel to form the Association that is our progenitor. For the rest of his life, Kirkbride pooled his thinking on the care of mental patients with that group, especially with Isaac Ray and Pliny Earle.

Although he was admired and respected, Kirkbride suffered a period of harrassment by a troublesome group led by a paranoid ex-patient who decided to use habeas corpus as a weapon. Scurrilous things were said and written about this gentle Quaker, who had the greatest respect for patients' rights. The following is from a letter in the *Reading Times and Dispatch*, November 13, 1871: "It appears to me that a man like this Kirkbride ought to be brought up on some charge that would be fatal to his liberty for the rest of his life" (quoted in reference 14, p. 125).

Another individual stated that

> If it is only necessary to get the certificate of two rascally physicians to certify to a person's insanity in order to incarcerate them in Kirkbride's hell then no man or woman in this community is safe. . . . We should feel very sorry to be compelled to counsel mob law, but it would be better that the walls of this earthly hell should be levelled to the ground than that sane people should be made the victims of its barbarity.

This type of prose and logic is still around today, although dressed up in a more scientific and humane garb and sounding a bit more temperate. Man's civil liberty, including the right of habeas corpus, is indeed precious and must be protected, but there is also a humane right to be taken care of when an individual is forlorn, alone, and unable to care for himself. Misunderstanding and fear of mental disease still lives in men's hearts, and it was used publicly against Kirkbride, one of the gentlest of men.

THE PIONEER OF FORENSIC PSYCHIATRY

Jacques Quen (15) said of another of our ancestors that

> with the possible exception of Adolf Meyer, no psychiatrist in 19th century America approached Isaac Ray's stature, or the breadth and magnitude of his contributions. . . . His concern for the welfare of the insane and the society they lived in evolved into a concern for justice on a broader scale. He was a reformer in a profound sense of the word. (15, p. 137)

In 1838, when Ray published his book *A Treatise on the Medical Jurisprudence of Insanity* (16), he was a general practitioner in a town of fewer than 2,500, far from any medical or legal center. Although Ray had no training at that time in either law or psychiatry, Quen has described this book as the first systematic exposition of medical thought about insanity in this country. Editions soon appeared in London and Edinburgh and the treatise was quoted extensively at the M'Naghten trial in England in 1843. Winfred Overholser said, "We have not even yet fully caught up with the reforms he advocated" (16, p. vii). When the fifth edi-

tion of the *Treatise* appeared in 1871, it was said that directly and indirectly it had done more than any other work to shape our laws and the decisions of our courts in regard to the insane. It was a pioneer work in American psychiatry and comparable in calibre to the textbook written by Rush.

Ray became superintendent of the State Hospital for the Insane at Augusta, Me., in 1841. Then, after careful study of the mental hospitals in Europe, he became the first superintendent of Butler Hospital in Providence, R.I. With the collaboration of the trustees of Butler and the help of his son, he made that hospital internationally known and respected.

In 1867, Ray reluctantly retired because of ill health, but even in his retirement years he was a power to be reckoned with. He confronted politicians and judges alike without fear or favor wherever he thought injustice was done, and Quen believes that he would have a few things to say to today's forensic psychiatrists.

THE FOUNDERS: A SUMMING UP

In our search for greatness we have of necessity been constricted, but we should keep in mind Earl Bond's opinion that the average ability of our Association's members has never been as high as was that of its 13 original founders. Albert Deutsch noted that they formed a group "alive with energy . . . great vitality, forceful will and abounding humanity. . . . Together, they tried to formulate their specialty into an integrated whole. . . . They eagerly strove to collect the facts and to use them to benefit their stricken fellow men" (quoted by Bond [14, p. 86]). I submit to you that this is a heritage of which we can be proud and which requires no apology.

The deficiencies of this group of founding fathers arose not so much from a lack of aims and ability as from the scarcity of knowledge. Theirs was of necessity a "here and now" philosophy. As physicians, they had only recently established their right to care for the insane over the claims of ministers and teachers. Also, medicine had only recently asserted that insanity was an illness and as such was within its province. Adolf Meyer reminded us that as late as 1894 a group of ministers in Germany wanted to be put in charge of mental patients. One cannot help but compare the situation with that today, as the medical model of mental illness is again under attack. In fact, the designation "medical model" seems to be used as an epithet by some.

THE CIVIL WAR PERIOD

We should pause to consider the admittedly low state of the discipline in the last half of the 19th century, as succinctly described by Zigmond Lebensohn:

> For reasons not altogether understood, the social upheavals caused by the industrial revolution led to changes in the social and cultural attitudes toward the mentally ill both in Europe and America after 1850, and most especially after the Civil War in our country. It was a time of incredible personal successes and catastrophic failures . . . of indifference to those who fell by the wayside, including the mentally ill. The moral treatment régimes in the earlier mental hospitals began to give away to this indifference. Hospital personnel were reduced to pawns in the rough and tumble politics of the day. Dirt, filth, overcrowding, and isolation from medicine became the rule, a rule that in the main prevailed until quite recent times. (17, pp. 381–382)

The story of the advancement of neurology in the Civil War period and of Weir Mitchell's stirring of the lethargy of the superintendents at the 50th anniversary of the founding of the Association in 1894 is interesting, but the details would be out of place here. To summarize, the appointment of neuropathologists to mental hospitals, the opening of a nursing school at McLean Hospital, and Adolf Meyer's insistence on careful case histories and mental, physical, and laboratory examinations all shed new light on the illnesses encountered and led to new and more hopeful concepts of mental disease.

Meyer kindled a spirit of research in the new American psychiatry that pulled the discipline out of its stagnant state and aroused the interest of a group of great men who adorned the field at the turn of the century. Unfortunately, there is not space in these pages to even list them, so I ask your permission to make the jump *quantum sufficit* to our present situation.

PSYCHIATRY TODAY

Van Wyck Brooks once said that an age is in chaos when one is living in it, and the past would be chaos too if it were not interpreted for us. To generalize about the present is a hazardous undertaking, but we are compelled to attempt it.

Psychiatry came out of World War II flush with great success. It had done an excellent job under difficult circumstances and had become an important sister discipline in medicine. But psychiatry came to be looked upon as the answer to everyone's problems. We had become too popular, and popularity is a heady wine. We became too diffuse and were pressed into undertaking too much. The results were inevitable, and we face them even now.

Today our discipline is divided within and faces a crisis of public confidence without. The question is asked: Does psychiatry have a future when it is looked upon by some of its critics as a policeman for the social order, "a covert penal system designed to maintain law and order"? (18). Eisenberg points out the contention of some "that mental ailments are problems of living and that people from his neighborhood are better able to treat the patient than doctors distant from him in status, education, and social class" (18, p. 1371). Others deny the whole concept of mental illness, and still others accuse the profession of being unrespon-

sive to the social problems of the day.

The opposite view is expressed by Henry G. Miller, a neurologist, who warns that "most of the abuses of the psychiatrist arise from his reluctance to restrict his activities to the field in which he is genuinely qualified to operate" (19). He notes that a psychiatrist is by definition one who treats mental disorders, not one who prevents wars, cures antisemitism, and battles similar evils. Every decent person abhors war, racism, and poverty and, like Rush, would do everything possible to correct these evils. But we were not trained in economics, sociology, or other disciplines that address problems as universal and old as civilized man.

Daniel Boorstin, Librarian of Congress, reminds us that ours is "the most motley and miscellaneous great nation of history, the first to use the full force of law and constitution and to enlist the vast majority of its citizens in a strenuous quest for justice for all races, creeds and ages" (20, p. 47). He believes that without a knowledge of the past we face the challenging present and uncertain future with nothing but abstractions and nebulous utopias, thus disregarding the "real chapter of history which can point the way toward that which is definitely humanly achievable."

The Move to Community Treatment

At this point, I would like to say a word or two about community mental health centers. I was on the committee that recommended their formation and chaired the committee that laid our ground rules for them. What we had in mind during those planning stages was the need to provide help closer to the homes of those who could not afford private psychiatric care, to have smaller, better staffed inpatient units, sheltered workshops, and emergency and follow-up outpatient psychiatric clinics—in short, to make available intelligent, compassionate care to all who needed help. It was modern day moral treatment, if you will, but somewhere along the line the coloration of some of the centers changed and a sociological-political outlook took over.

Pari passu with this change, there came into being the logical fallacy that since bad hospitals are bad for patients, any hospitalization is bad for patients and should be avoided entirely or made as brief as possible. Consequently, hospitals discharged many patients too soon, and the community centers were not yet equipped to treat them. Many of these patients were sent home, and in some cases children were exposed to psychotic individuals in various states of pharmacologically controlled remission. The end results of this are yet to be evaluated. Many discharged patients had no homes to go to or had homes that would not accept them, and they therefore gravitated to the streets, untreated and in danger of victimization. I will not go into a description of what is happening in some of our larger cities—we are all aware of it, and it is depressing. As the Director of the Psychiatric Section of Bellevue Hospital recently said, "some of it is straight out of Kafka."

A Return to Medicine

Amid the quarrels and cleavages of recent years, there have been remarkable resurgences in our understanding of the basic biological underpinning of some of the mental disorders. Psychopharmacology, neurophysiology, chemistry, and endocrinology have all contributed, and the work in these areas points to the direction we should take—a return to medicine, retaining mastery of psychotherapeutic techniques and psychodynamic understanding and keeping in mind all of the things we have learned through the years from our patients. Arnold Ludwig describes the problem eloquently:

> What is taking place is actually not psychiatry: the field has become a hodgepodge of unscientific opinions, assorted philosophies, and "schools of thought", mixed metaphors, role diffusion, propaganda, and politicking for "mental health" and other esoteric goals—all intermeshed with islands of sound, responsible psychiatric practice. (21, p. 603)

Ludwig adds that the only solid foundation for psychiatry is the medical model, which need not be limited strictly to established facts or scientific principles. "Medicine, as practiced both past and present, represents a blend of empirical observations, scientific knowledge, unproved assumptions, and folklore." What distinguishes it, Ludwig notes, is a philosophic orientation toward dealing with symptoms and signs that represent disease and the belief that eliminating these causes will result in cure or improvement.

There are volumes of experiential and medical documents confirming the inseparability of mind and body, but the capacity of the mind to regulate and heal itself and the body is constantly given short shrift in medical practice. For more than three decades, psychiatrists have been in daily consultation with our medical and surgical brethren and it is in the general hospital, the small private hospital, and the community ventures, properly oriented, that the future of psychiatry lies. I have no quarrel at all with the thought that in the future a great deal of what is now called "community mental health care" will be delivered by nonpsychiatric professionals. Some of them may indeed be better prepared than are psychiatrists to advise patients on problems of daily life. Psychiatrists will be reserved primarily for situations that clearly demand their expert medical skills. Eisenberg's comment on this subject is worthy of our attention:

> Psychiatry at its best is a paradigm for the general medical practice of the future. This may seem an outlandish claim for a field which boasts so few spectacular advances. Yet I believe it to be true because psychiatric practice deals with human distress in a context that must include the psychosocial as well as the biological. There are no imperialistic aims behind this claim. Quite to the contrary, in so far as psychiatry is successful in clarifying the psychobiological bases of health and illness, that knowledge will pass into the domain of the generalist and

> the psychiatrist will join other specialists in the secondary and tertiary cadres of the health system. (18, p. 1375)

There are many impending changes that will require all of us to keep abreast of medical progress. First are the coming requirements of continuing education and the possibility of relicensure. Second are the Professional Standards Review Organizations, one feature of which is particularly advantageous to psychiatry, namely that the reviews must take place within the framework of the rest of medicine. Thus we will be pushed back into the mainstream of medicine, and closer association with our medical confreres will be necessary as greater specificity of diagnosis and treatment is required of us.

Definite legal authority and accountability of the physician will also be called into play, and no one else can assume those responsibilities or even share them. Good medical care will be required. There are potential dangers, of course, e.g., the possibility that standardization will override good clinical practice, but one hopes that these dangers will be kept to a minimum.

THE FUTURE

How are we to accomplish the important move of psychiatry back into medicine? Perhaps we can make use of the phenomenon of complementarity, the art of encompassing different aspects and different approaches to a problem and utilizing the essentials of each to arrive at a workable answer.

Thomas Duane, in welcoming the freshman class of Jefferson Medical College in September 1973, spoke of Niels Bohr, who was able to reconcile the seemingly conflicting views of his fellow physicists on a question of the composition of light by noting that these views actually complemented each other. Bohr's great contribution was that he could see the overlap in the experiments and ideas of such men as Planck, Huygens, and Einstein and thus bring order out of chaos. He perceived that all of his colleagues were right and all were wrong, i.e., that each viewpoint was incomplete when expressed unilaterally. Realizing that these brilliant men had not carried their thinking to the next logical step, Bohr introduced into quantum theory one of its basic tenets, the theory of complementarity.

Bohr's contribution was not a compromise; rather, it was a gathering together of incomplete ideas. Bohr realized that this approach could be applied to many phenomena besides atomic physics. Duane believes the principle of complementarity should become a cornerstone of twentieth-century philosophy, and I present it to you as a hopeful vista for psychiatry.

Psychiatry is in trouble today because some of its practitioners are "hooked" on various seemingly contradictory approaches. But the quintessence of medical practice is complementarity, and for psychiatry—to use the vernacular—the principle "gets it all together." Complementarity encompasses both the science and art of medicine. There has been a right and wrong to the various theories put forth to the psychiatrist—the art is to hold fast to that which is right and which is good. Complementarity, therefore, should be our watchword.

In this Bicentennial year, I give you a rather kaleidoscopic view of our specialty, an admittedly intimate, personal view. We recall the axiom that progress moves not in a straight line but rather in the form of a spiral, each time around a notch or two higher. Although many of our patients are on the streets, as patients were 200 years ago, our research has advanced to the point where we can help most of them and prevent chronicity—if we can devise methods to get them into treatment.

Franklyn Arnhoff examined present social policy toward mental illness and found an indiscriminate shift from hospital to community treatment. He noted that

> Reinforcement for this position is provided by the most limited type of cost accounting and administrative statistics, from which it is fallaciously concluded that economies will be realized by such policies. Thus it is made to appear that humanitarian ends can be achieved at lower cost, an outcome that has obvious popular appeal. (22, p. 1278)

Arnhoff also noted that this approach will eventually result in the need to rediscover public mental institutions because there are unfortunately still large numbers of chronic psychotics who cannot survive outside an institutional setting.

Thus we will cross the same point in the spiral that we crossed 200 years ago, but this time at a much higher point. The situation is much more hopeful today because we have advanced our scientific knowledge and, one hopes, learned from past errors. Just as Weir Mitchell shook up the superintendents of the mental hospitals in 1894, it is now time for some of us to shake up the profession again by telling them a few homely truths. We have two givens: 1) there are many thousands of individuals who are emotionally and mentally distressed; and 2) we are physicians trained to care for the individual in his entirety—psyche and soma. If we stay within the confines of our discipline we can move in any direction that will be to the advantage of our patients. When we go beyond it, we become like any other stranger. There is a dignity to our specialty and a dignity to our heritage, and it is unwise to turn our backs on them.

Lastly, in these days of renewed interest in ethics, let me recall to you the advice given in 1716 by Sir Thomas Browne of *Religio Medici* fame:

> Live by old Ethicks and the classical rules of honesty. Put no new names or notions upon Authentic Virtues and Vices. Think not that morality is ambulatory, that Vices in one age are not Vices in another, or that Virtues which are under the everlasting Seal of Right Reason may be stamped by opinion. And therefore, though vicious times

invert opinions of things and set up new Ethicks against Virtue, yet hold thou unto old Morality.

The Broad Role of Ego Functions Assessment

BY LEOPOLD BELLAK, M.D., AND MICHAEL SHEEHY, M.D.

The need for accurate assessment and accountability is of paramount professional concern to psychiatry. The authors state that ego functions assessment (EFA) is a reliable and valid quantitative technique, useful for these purposes in a variety of psychiatric settings. They suggest the various uses of EFA in five such areas: Professional Standards Review Organizations (PSRO) and third-party funding, forensic psychiatry and legal responsibility, the monitoring of psychotherapeutic drugs, research and planning in psychotherapy, and psychological testing. The authors conclude that EFA is a dynamically sophisticated and easily learned form of mental status examination and that its refinement by extensive use and simplification is likely.

THE CURRENT VIGOROUS DEMAND for greater accuracy in psychiatric thought has imposed a broad need for methods of personality evaluation that are statistically reliable and valid and at the same time useful in a considerable number of clinical settings. Ego functions assessment (EFA) constitutes an innovative means of meeting this need.

Because they serve as interlocking operational definitions of the psychoanalytic construct of the ego, the ego functions are embedded in a theory of personality that, despite years of critical assault, continues to influence the treatment of large numbers of psychiatric patients. The proper understanding and application of the operational nature of ego functions should go far to answer the objections that psychoanalytic theory has paid insufficient attention to the nature and logic of the relationship between abstract statements about the patient and observable clinical behaviors, a point recently emphasized by Chodoff (1).

Bellak and associates (2, pp. 74–79) described 12 ego functions. These are listed in appendix 1. In their study of schizophrenic patients, neurotic patients, and normal subjects, Bellak and associates demonstrated that the interrater reliability between two judges formally evaluating 100 individuals from these three categories (50 schizophrenic patients, 25 neurotic patients, and 25 normal subjects) on a 13-point scale ranged between .61 for the ego function of stimulus barrier and .88 for autonomous functioning, with a mean correlation of .77 (2, p. 302). Although these figures stem from the use of a specifically designed interview manual, ratings based on ordinary psychotherapeutic sessions allow for an interrater reliability of .72 (3).

The ability to make reliable ratings of different kinds of individuals without formally administered test instruments or rigid and unusual constraints on an interview represents a major asset of EFA and encourages its use in clinical treatment settings. Scoring is done by matching the findings of the clinical interview to the descriptive language of the rating manual, which contains detailed and specific anchor definitions for alternate scale points (2, pp. 438–442). Clinical findings representing an intermediate stage between adjacent points, e.g., 3 and 5, would be scored as such, i.e., 4. The same numerical point score for different ego functions indicates approximate equality in adaptive level. A score of 11 indicates "average" functioning as defined by the absence of any notable maladaptation or pathology but short of optimal functioning. Point 1 (maximal impairment) and point 13 (optimal functioning) serve primarily to orient the clinician to the possible extremes; only rarely would such points apply to an individual patient. An illustration from the manual (a description of the scoring of reality testing component A, the distinction between inner and outer stimuli) is given in appendix 2.

For clinicians who are not psychoanalytically oriented, EFA may be conceptualized as a standardized version of a mental status examination with substantial practical usefulness. The theoretical grounding of EFA in the matrix of interlocking psychoanalytic hypotheses, however, permits one who is so inclined to further relate ego functions to the nature of drive quality and quantity as well as to superego structures and the remainder of psychoanalytic theory. Reality testing, for instance, may be affected by either drive or superego. By way of experimental illustration, Levine and associates (4) found that hungry individuals shown tachistoscopic pictures perceived food more accurately (showing good reality testing due to motivated perceptual vigilance) than nonhungry control subjects when food was present in the pictures, but the hungry individuals also saw food when none was present (showing poor reality testing due to the need for wish fulfillment).

Within the ego itself any given component function can influence one or more of the other functions. A general idea of the potential impact of disturbed reality testing on thought processes and judgment is quite

Dr. Bellak is Clinical Professor of Psychiatry and Dr. Sheehy is Assistant Professor of Psychiatry, Albert Einstein College of Medicine, Bronx Municipal Hospital Center, 1165 Morris Park Ave., Bronx, N.Y. 10461.

clear on the surface, but EFA allows more exacting assessment of the extent of the impact and, in turn, its relationship to other areas of ego functioning (2, pp. 105, 106). Without systematic EFA, many of these relationships may be far from obvious.

Although discussion in this paper and elsewhere often refers not only to specific ego functions but to an "ego" in some structural sense as well, the statistical analysis that provides the logical framework for EFA as a reliable and valid technique of assessment also justifies the concept of separate functions in a structural whole. This analysis demonstrates that the ego functions can vary with sufficient independence in a given individual to warrant separate identities while sufficient interrelationships exist to sustain conceptualizing the ego as a structural unit. Comparison of EFA with the Wechsler-Bellevue Intelligence Scales (WAIS) shows that the 11 subfunctions of intelligence delineated in the WAIS show a mean intercorrelation of .52 and the 12 ego functions assessed in schizophrenic patients, neurotic patients, and normal subjects show a mean intercorrelation of between .46 for schizophrenic patients and .61 for neurotic patients (2, p. 312). Such data support the construct of a whole composed of independent but overlapping subfunctions as much in the realm of the ego as in that of intelligence.

Keeping this briefly explained theoretical context in mind, we propose the use of EFA in the following five areas of psychiatric concern: 1) Professional Standards Review Organizations (PSRO) and third-party funding, 2) forensic psychiatry and legal responsibility, 3) the monitoring of psychotherapeutic drugs, 4) research and planning in psychotherapy, and 5) psychological testing. Although EFA is applicable to other areas of psychiatric endeavor, we believe that illustrations pertaining to these five areas serve to highlight its principal assets.

It is something of a truism to point out the contribution that reliable and valid assessment measures can make to any area of psychiatry. Nevertheless, it is the purpose of this paper to clarify the particular assets of EFA that are distinct from other instruments and that provide a perspective not found elsewhere.

PSRO AND THIRD-PARTY FUNDING

The development of standards for care is in the forefront of psychiatric concern today. Specifications for therapy and its outcome require definition.

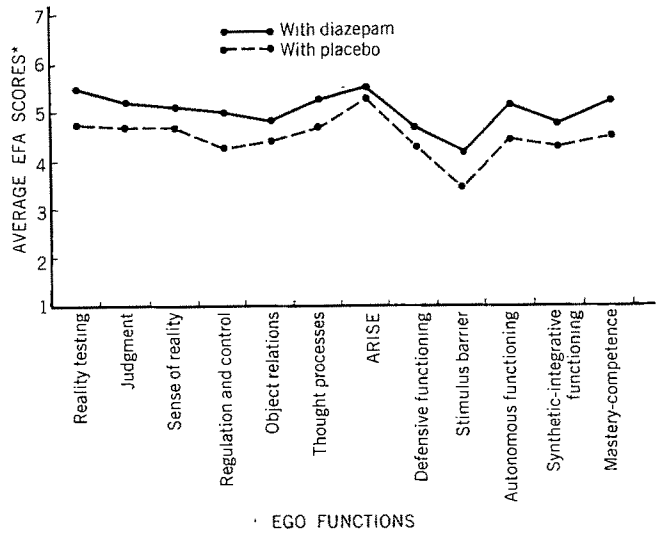
Unlike diagnostic statements and typical symptom checklists, EFA measures the level of function at different times as well as the capacity for adaptation in such critical areas as judgment, impulse control, reality testing, and interpersonal relations. These are among the measurements that are most useful in making decisions about admission or discharge at inpatient facilities. Correctly identified, a patient's adaptive capacity should have clear consequences in determining the nature and setting of his or her treatment and, in turn, its cost—both in social and in dollar terms. One patient may require a costly hospitalization with its attendant disruption of work, family relationships, economic status, and self-esteem, while another with identical manifest symptoms may require outpatient treatment only. Most psychiatrists make such discriminations on grounds that range from the intuitive to the reasonably objective; however, anyone familiar with hospital practice is only too aware of the differences among psychiatrists in their decisions about admission or discharge. EFA provides a valid and reliable scheme for logical observation that can be keyed to hospital policy and can be clearly stated to government agencies, insurance companies, or other third-party payers.

Although certainly not a requirement of PSRO, the question of treatment results surely will become a matter of increasing concern to organizations funding psychiatric care. Symptoms are an excellent reference point for determining treatment results in any field of medicine. Loss of symptoms, however, may deceptively imply improvement (e.g., loss of chancre); continued manifest symptoms, on the other hand, may coexist with improved functioning and adaptive capacity, an area especially accessible to EFA. In addition, outpatient treatment often continues well past the time when initial symptoms abate; justification of the duration of therapy must then depend on measurements other than symptom relief alone. Problems such as the inability to sustain a close interpersonal relationship, as in marriage, are common in outpatient clinics and private practice settings but frequently fit into some of the least specific psychiatric diagnostic concepts, such as adjustment reaction of adult life or marital maladjustment. The degree of dysfunction in such cases is at present poorly specified, which in turn makes for great difficulty in evaluating change objectively. This very kind of evaluation may soon be a requirement when third-party payment is involved.

FORENSIC PSYCHIATRY AND LEGAL RESPONSIBILITY

Forensic psychiatry and the concept of legal responsibility represent a much embattled area. Aside from arguments about the role of psychiatrists in court, the specific nature of their testimony—especially their inclination toward conclusive remarks based on authority rather than explicit reasoning—has been widely attacked. Besides providing a statistically tested tool for evaluating a defendant in a format that exposes its logic to the jury, EFA would permit the pinpointing of specific behavioral difficulties. For instance, a defendant whose reality testing, thought functions, and judgment had been demonstrably normal throughout most of his life might be shown on formal EFA to have poor impulse control. An objective finding of this sort might point toward further investigation, e.g., in the area of

minimal brain dysfunction. Because it is the capacity of an individual to control his or her behavior that primarily determines legal responsibility, EFA seems to be an exceptionally useful tool in that it measures this capacity specifically from a number of reference points.



Outside the sphere of criminal responsibility, the evaluation of an individual in regard to the capacity to make a will or enter a contract requires a determination of his or her judgment and capacity to anticipate the likely consequences of his or her intended behavior as well as a number of other mental functions. Formal EFA makes the evaluation of these capacities explicit and provides a statistical understructure of reliability as well, a point of no small importance to a court system potentially deluged with often murky expert testimony.

THE USE OF PSYCHOTHERAPEUTIC DRUGS

Drug treatment of psychiatric conditions continues to suffer greatly from arbitrariness of prescription. The use of research criteria such as those of Feighner and associates (5) provides clarity of diagnosis and a rational basis for experiments in treatment but leaves undiagnosed many patients who fail to satisfy the strict criteria. Response to drugs can constitute a useful touchstone for diagnosis, as Klein and David (6), among others, have urged. The effects of neuroleptics on various ego functions in research studies can clarify diagnostic subcategories as well as give a clinical opportunity for EFA to identify the specific benefits of a drug to an individual patient. The following case report might clarify this point:

Case 1. A woman about 40 years old with a diagnosis of severe psychoneurosis was seen for psychotherapy twice a week for five and a half months. During this time the patient was alternated on a double-blind basis between 10 mg of diazepam (Valium) three times a day and matching placebo. Each medication was given for one or two weeks at a time, with each such length determined on a random basis. The patient was rated blindly for each ego function at each treatment session, using a 7-point scale. Only defined anchor points were used in this scale (convertible to the current standard 13-point scale by multiplying each score by 2 and subtracting 1). This patient's average scores are shown in figure 1 and table 1.

FIGURE 1
Comparison of Average EFA Scores of a Patient Treated with Psychoanalytic Therapy and Alternating Diazepam and Placebo

*1=maximal impairment; 7=optimal functioning.

TABLE 1
Comparison of Average EFA Scores of a Patient Treated with Psychoanalytic Therapy and Alternating Diazepam and Placebo

Ego Function	Average EFA Scores, by Drug Given		Significance*
	Diazepam	Placebo	
Reality testing	5.52	4.86	p<.01
Judgment	5.41	4.83	p<.01
Sense of reality	5.26	4.81	p<.05**
Regulation and control of drives, affects, and impulses	5.00	4.31	p<.01
Object relations	4.93	4.60	n.s.
Thought processes	5.35	4.70	p<.01
ARISE	5.57	5.53	n.s.
Defensive functioning	4.87	4.24	p<.01
Stimulus barrier	4.02	3.55	p<.01
Autonomous functioning	5.09	4.48	p<.01
Synthetic-integrative functioning	4.89	4.36	p<.05
Mastery-competence	5.09	4.55	p<.01

*By two-tailed t test.
**By one-tailed t test.

The use of EFA for this patient demonstrated a rather even level of improvement in most functions with the exception of object relationships and ARISE, which did not reach the level of statistical significance (3). The use of EFA also demonstrated a rather smooth level of improvement in nearly all of this patient's ego functions. This improvement could not have been deduced exclusively from the anti-anxiety effects of diazepam or from psychotherapy alone.

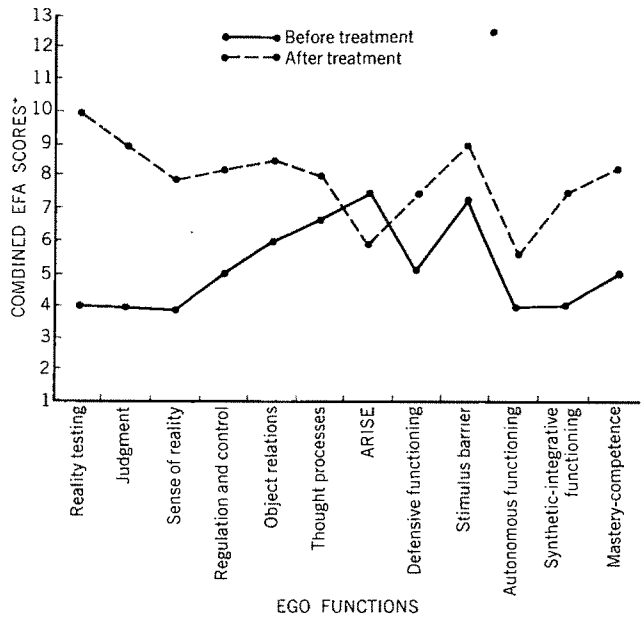
In another individual, careful EFA performed before treatment was started might point to a specific disturbance of impulse control as a particularly exaggerated problem, suggesting the use of a phenothiazine to decrease aggressivity or to facilitate its management. In other instances in which a disturbance in the sense of self is identified, e.g., in a borderline patient, phenothiazines may be contraindicated because of their tendency to aggravate this disturbance in nonpsychotic patients. Assuming poor impluse control and a disturbed sense of self are identified together by EFA, drug therapy could be directed at the symptom that ei-

ther was quantitatively greater or appeared to most severely impair the other ego functions.

In addition, the choice of two combined drugs and their dose levels might be determined with the aid of EFA. For example, the depressed patient who historically presents evidence of psychotic thinking could be given a baseline EFA and treated with tricyclic antidepressants, with phenothiazines added rationally almost by titration, depending on the changes in thought processes and the sense of reality that appear on follow-up EFA.

RESEARCH AND PLANNING IN PSYCHOTHERAPY

Plagued by problems of idiosyncratic content as well as different conceptual models of cause and cure, psychotherapy has proven a frustrating field for the researcher. The following case illustrates the application of EFA to before/after evaluation:



Case 2. The patient was a 24-year-old man who ran through the streets of a West Coast town one evening singing, shouting, disrobing, and setting fire to his clothes. He was hospitalized after being apprehended by the police. Just before this event he had suffered business and romantic reverses and developed grandiose ideas that appeared compensatory (i.e., he expected to be sent to Viet Nam to end the war). Simultaneously, he became afraid that any number of people might interfere with his plans; he felt spied on by the CIA and the FBI. He thought he was being observed on television and that people could read his mind. His apprehension by the police served to confirm these ideas.

After a brief hospitalization on the West Coast he was returned to the East Coast on a regimen of 800 mg of thioridazine (Mellaril) daily. He was hospitalized on the East Coast, EFA was performed, his medication was reduced, and psychotherapy was started. Because he improved in two weeks, the patient was discharged and treated in psychoanalytic therapy for the next two years. One year after he terminated treatment because of parental pressures he was reassessed. All EFA was done by two independent raters (2, pp. 385–391). The correlation of their scores was .67 ($p < .05$). Their combined ratings are shown in figure 2 and table 2.

Although this before/after evaluation cannot distinguish the effects of psychotherapy from spontaneous remission, the consequences of phenothiazine treatment, or the impact of current social factors, the data for this patient clearly demonstrate marked improvement in reality testing, judgment, sense of reality, regulation of drives, mastery-competence, and defensive and synthetic functions. The remaining ego functions did not show statistically significant changes. Clinically, the patient appeared free of his previous symptoms, was employed, and had a satisfying social life.

The problems of distinguishing treatment effects from changes that are independent of specific treatment are dilemmas of research design. Using EFA, however, with the patient as his or her own control, the effect of interpretative and interpersonal efforts can be studied at close range for their consequences at the same time that an objective record of general progress or deterioration is assembled to provide corrective feedback in the treatment process.

FIGURE 2
Comparison of Combined EFA Scores of a Patient Rated by Two Evaluators Before and After Two Years of Psychoanalytic Therapy

*1=maximal impairment; 13=optimal functioning.

TABLE 2
Comparison of Combined EFA Scores of a Patient Rated by Two Evaluators Before and After Two Years of Psychoanalytic Therapy

Ego Function	Combined EFA Scores, by Time of Evaluation: Before Therapy	After Therapy	Significance*
Reality testing	4.0	10.0	$p<.01$
Judgment	4.0	9.0	$p<.01$
Sense of reality	4.0	8.0	$p<.01$
Regulation and control of drives, affects, and impulses	5.0	8.0	$p<.05$
Object relations	6.5	8.5	n.s.

Synthetic-integrative functioning	4.0	7.5	$p<.01$
Mastery-competence	4.0	8.0	$p<.01$

*By chi-square test with correction for continuity.

PSYCHOLOGICAL TESTING

Psychological testing remains a very valuable asset in patient assessment and an important guide to therapy as well. There must be a close and rational relationship between psychodiagnostic test data and diagnostic inference, preferably given in a report that links conclusions to explicit primary patient responses. EFA

clearly has a role to play in analysis of the data from the current battery of standard tests (7). EFA is designed in a fashion that makes its workings operational and available for inspection and countercheck. The relationship it bears to the larger structure of psychoanalytic hypotheses makes it especially useful in planning and evaluating treatment.

CONCLUSIONS

Although it presents only a partial answer to some of the numerous problems of assessment facing psychiatry, EFA does constitute a statistically reliable and valid means of evaluating personality in operation, which makes it useful in many areas of psychiatry.

APPENDIX 1
Ego Functions and Their Components

1. *Reality Testing*
   a. Distinction between inner and outer stimuli
   b. Accuracy of perception of external events
   c. Accuracy of perception of internal events

2. *Judgment*
   a. Anticipation of consequences of intended behavior
   b. Manifestation of this anticipation in behavior
   c. Appropriateness of behavior to external events

3. *Sense of Reality*
   a. Extent of derealization
   b. Extent of depersonalization
   c. Self-identity and self-esteem
   d. Clarity of boundaries between self and world

4. *Regulation and Control of Drives, Affects, and Impulses*
   a. Directness of impulse expression
   b. Effectiveness of delay mechanisms

5. *Object Relations*
   a. Degree and kind of relatedness (narcissistic attachment or symbiotic object choices)
   b. Primitivity versus maturity
   c. Degree to which others are perceived independently of self
   d. Object constancy

6. *Thought Processes*
   a. Memory, conception, and attention
   b. Ability to conceptualize
   c. Primary versus secondary process as reflected in communicative language

7. *Adaptive Regression in the Service of the Ego (ARISE)*
   a. Ability to regressively relax cognitive acuity
   b. Ability to allow new configurations to emerge in thinking

8. *Defensive Functioning*
   a. Weakness or obtrusiveness of defenses
   b. Success or failure of defenses

9. *Stimulus Barrier*
   a. Threshold for stimuli
   b. Effectiveness of management of excessive stimulus input

10. *Autonomous Functioning*
    a. Degree of freedom from impairment of primary autonomy apparatuses
    b. Degree of freedom from impairment of secondary autonomy apparatuses

11. *Synthetic-Integrative Functioning*
    a. Degree of reconciliation of incongruities
    b. Degree of active relating together of events

12. *Mastery-Competence*
    a. Competence (how well a person performs in relation to his or her capacity to actively master and affect his or her environment)
    b. Feeling of competence as measured by person's expectations of success on actual performance
    c. Discrepancy between actual competence and feeling of competence

APPENDIX 2
Scoring of Reality Testing Component A: Distinction Between Inner and Outer Stimuli

Point 1 (maximal impairment)
Hallucinations and delusions pervade.
Minimal ability to distinguish events occurring in dreams from those occurring in waking life and inability to distinguish among idea, image, and hallucination.
Perceptual experience is grossly disturbed (e.g., moving things look still and vice versa).

Point 3
Hallucinations and delusions are severe but limited to one or more content areas.
Patient may show considerable doubt about distinguishing whether an event really happened in his or her mind or in a dream.

Point 5
Illusions are more likely to be found than hallucinations.
Patient may be aware that he or she sees and hears things that are not there, but he or she knows that others do not see or hear them.

Point 7
Projections of inner states onto external reality is more likely than frank hallucinations or delusions.
A "stimulus-bound" reality testing may occur at the cost of libidinal investments and gratification.

Point 9
Confusion about inner and outer states occurs mainly upon awakening, going to sleep, or under severe stress.

Point 11
Inner and outer stimuli are well distinguished.
Occasional denial of external reality in the service of adaptation.

Point 13 (optimal functioning)
Clear awareness of whether events occurred in dreams or waking life.
Correct identification of the source of cognitive and/or perceptual content as being idea or image and accurate identification of its source as internal or external.
Distinction between outer and inner percepts holds up even under extreme stress.
Checking one's perceptions against reality occurs with a very high degree of automaticity.

Prompt Publication Policy

The *Journal* would like to remind authors who are particularly interested in early publication (whether to establish priority of an idea, reveal innovative results of new research, or for other pressing reasons) of its prompt publication policy. Under this policy, short (maximum of six double-spaced pages) manuscripts will be considered for publication in the Brief Communications section of the first available issue. These manuscripts must still undergo expert scrutiny before being accepted, and two months must be allowed for the printing process. However, the time required for publication of these short articles can be lessened considerably.

Authors who would like to have their manuscripts considered under this policy should indicate this desire, as well as the reasons for it, when they submit their manuscripts.

Depression and the Reintegration Phase of Acute Schizophrenia

BY PATRICK T. DONLON, M.D., RICHARD T. RADA, M.D., AND KRISHAN K. ARORA, PH.D.

The authors found moderate to severe depression in 60% of a group of schizophrenic patients experiencing acute decompensations (N=30). The course of the depression was followed over an 8-week period, during which patients were treated with depot fluphenazines. There was a statistically significant reduction in depression that closely paralleled the correction of the cognitive disorder. The authors discuss problems in identifying and quantifying depression during acute schizophrenic decompensation and suggest that the Hamilton scale anxiety/depression factor and the BPRS depression factor may be useful diagnostic tools.

ALTHOUGH DEPRESSION may appear at any point during the course of schizophrenia, it is characteristically more prevalent and severe during periods of psychotic exacerbation (1). These periods may be divided into two general phases: decompensation and reintegration. A previous report (2) described four phenomenological stages of the decompensation phase: 1) early and fluctuant cognitive and perceptual disturbance, 2) the ego's attempt to cope and defend against psychotic decompensation and the depression frequently associated with it, 3) the acute breakdown in reality testing, with panic and marked dysphoria, and 4) the more chronic and quiescent stage associated with marked autistic preoccupation and idiosyncratic interpretation of stimuli and concepts. Depression normally peaks with the transition from the second to the third stage. However, if the course of schizophrenia continues unabated and moves into the fourth stage, clinical evidence of depression and of other forms of subjective distress is much less apparent. The phenomena and stages seen during the reintegration phase are similar, although they occur in reverse order (2, 3). Depression is commonly associated with both the reintegration and postpsychotic periods (4).

The purpose of this study was two-fold. First, we investigated the relationship between the depressive and cognitive component in reintegrating schizophrenic patients. Second, we examined the efficacy and safety of a depot phenothiazine—either fluphenazine enanthate (FE) or fluphenazine decanoate (FD)—with acutely decompensated schizophrenic patients. This paper will present only those aspects of the study relevant to the first purpose; data on the efficacy and safety of the fluphenazines are presented elsewhere (5).

Dr. Donlon is Associate Clinical Professor, Department of Psychiatry, University of California, Davis, School of Medicine, 2252 45th St., Sacramento, Calif. 95817. Dr. Rada is Associate Professor of Psychiatry and Vice-Chairman, Department of Psychiatry, University of New Mexico School of Medicine, Albuquerque, N.M. Dr. Arora is Research Statistician, E.R. Squibb and Sons, Inc., Princeton, N.J.

The authors wish to thank Robert Kellner, M.D., University of New Mexico, for his suggestions on this paper.

METHOD

The study was conducted on the inpatient service of the University of California, Davis, Sacramento Medical Center.

After giving informed consent, 41 acutely decompensated schizophrenic patients were randomly assigned to treatment with either FE or FD in a double-blind, flexible-dosage protocol. All patients were diagnosed as having paranoid or undifferentiated schizophrenia. Twenty-four patients had previously been stabilized on neuroleptic medication at some time before their hospitalization. None of the patients had a history of significant affective disorder, and individuals with a history suggestive of manic-depressive illness or schizo-affective disorder were excluded from the study.

The study period was 8 weeks; patients discharged before that time were followed on an outpatient basis. Patients were seen daily during hospitalization and at least weekly after discharge.

Evaluation instruments included the Brief Psychiatric Rating Scale (BPRS) (6), the Clinical Global Impression Scale (CGI), the Hamilton Rating Scale for Depression (7), and the Zung Self-Rating Depression Scale (8). All of these scales rate severity of symptoms from absent to extreme, with higher numbers representing greater pathology. The BPRS and CGI scales range from 1 to 7. The Zung scale ranges from 1 to 4 and the Hamilton scale from 0–2 to 0–4. Patients were rated when they entered the study, once a week during the first 4 weeks, and at 6 and 8 weeks after admission. Baseline ratings were, in general, done on the day of hospitalization and in all cases were completed before administration of study medication.

Eighteen of the patients underwent psychometric testing at the beginning and end of the study. The tests included the Benjamin Proverb Test, the Discomfort Relief Quotient Rating, and the Looseness of Association Index, which is derived from a 5-minute free association interview (9).

A 4-point global drug efficacy rating, ranging from 1 (marked therapeutic effect) to 4 (unchanged or worse) was made at the end of the 8-week period.

RESULTS

Of the 41 patients who started the study, 30 completed the first month. Three patients dropped out during the second month (2 left the treatment area and 1 requested oral medication). Thus 27 patients completed the 2-month study; data will be presented for the 30 subjects who completed at least 1 month.

There were 12 men and 18 women ranging in age from 18 to 57 years (mean=30). Most subjects were in social classes IV and V (10).

Evaluation of Antipsychotic Response

There were no significant differences in the therapeutic efficacy of fluphenazine enanthate and fluphenazine decanoate (5). Each was highly effective in producing rapid amelioration of acute psychotic symptoms and continued symptom remission. On the CGI, all patients treated with FE and FD showed statistically significant ($p<0.01$) improvement at 4 weeks, 8 weeks, and at discharge. Patients on FE, however, became slightly worse after discharge, then improved again. The 18 patients who had been given psychometric tests showed a striking and uniform decrease in cognitive disorganization associated with neuroleptic administration (9).

Evaluation of Depression

Depression, as rated on the BPRS and the Hamilton scale, was greatest at baseline and decreased over the study period. The reduction in depression closely paralleled improvement in cognitive symptoms on the BPRS. There was no significant difference in degree of baseline depression between the FE and FD groups on either measure.

The BPRS data (table 1) demonstrate a striking relationship between the reductions in depression and thought disorder. Both were most marked in severity at baseline and decreased over time. The 1 patient who deviated from this pattern was a 26-year-old man whose depression could be more appropriately termed postpsychotic. He had no history of affective disorder and his premorbid personality was shy, sensitive and withdrawn. He was experiencing his first psychotic episode and he had never been on neuroleptic medication.

The data for the 4 BPRS depression items (11) and

the 5 thought disorder items (see table 1) were subjected to analysis of variance (repeated-measures) both as individual items and as factors. The baseline scores suggest that the patients in the two drug groups were about equally ill. Both drugs showed statistically significant ($p<.05$) efficacy on all but 1 item as the study progressed. Anxiety scores for patients on both drugs remained about the same.

At baseline, 12 patients had a mean depression score of 3 or less, 17 patients, greater than 3 but less than 5, and 1 patient scored between 5 and 7. Thus 40% of the subjects were not significantly depressed as measured by the BPRS, 57% were moderately depressed, and 3% were severely depressed. At termination, only 8 patients (27%) had a depression score above 3, indicating a marked reduction in clinical depression for the group. Of the 3 subjects who were followed for only 4 weeks, 1 was rated as moderately depressed and 2 as not significantly depressed at termination.

The Hamilton scale yielded similar results (see table 2). This scale can be divided into four factors: sleep disturbance (early, middle, and late insomnia), somatization (somatic anxiety, somatic symptoms-gastrointestinal, somatic symptoms-general, genital symptoms, and hypochondriasis), anxiety-depression (depressed mood, guilt, suicidal ideation, agitation, and anxiety), and apathy (loss of interest in work, activity, and insight). Average scores for each factor are reported in table 2.

The baseline scores indicate that patients treated with FD were initially as sick or somewhat worse than those treated with FE. Efficacy of fluphenazine is obvious from the fact that both drugs showed statistically significant ($p<.05$) improvement across time for all factors except somatization for FE. The patients on FE showed transient reduction in somatic symptoms but returned to baseline level at termination.

At baseline, 15 patients had a mean score of 1 or less on the anxiety/depression factor, 12 patients had scores between 1 and 2, and 3 patients, greater than 2. At termination, only 5 patients (17%) had scores above 1, a marked decrease for the group.

Table 3 gives mean index scores on the Zung scale—baseline scores were not obtained because of the patients' grossly psychotic states. There were moderate fluctuations in the scores for the various rating periods but no significant changes for either group.

DISCUSSION

Sixty percent of these schizophrenic patients experienced depression as a prominent component of their acute schizophrenic process, a finding that confirms previously reported data (2). In this study, depressive symptoms were most marked during overt schizophrenic decompensation. Reduction in depression is closely correlated with the remission of the cognitive disorder.

Comparatively little attention seems to have been given by researchers and clinicians to the depressive component of schizophrenia. This may be due in part to the difficulty of diagnosing and quantifying depression during the acute schizophrenic process. Diagnosis can be difficult because schizophrenia and depression share certain signs and symptoms, including psychomotor disturbance, hypochondriasis, appetite and sleep disturbances, apathy, impulse control impairment, and weight loss. If the diagnostician is biased in favor of one of the diagnoses, he may use these overlapping symptoms to further substantiate his initial impression. The addition of neuroleptic medication can complicate the diagnosis because drug-induced aki-

nesia can produce a clinical picture of apathy and psychomotor retardation that resembles depression.

In addition, depression (like other affects) may be more labile and transitory in overtly psychotic schizophrenics than the persistent mood seen in depressive disorder. Further, the depressive symptoms may be overshadowed by more overt cognitive and behavioral disturbances.

Therefore, in order to identify and quantify depression in schizophrenia, we focus on depressive mood and attitude (guilt, remorse, self-degradation, suicidal concern, pessimism, despair, helplessness, and hopelessness). We feel that the depressive factor of the BPRS and the anxiety/depression factors of the Hamilton scale are more useful in identifying and quantifying depression than the Hamilton somatization, apathy, and sleep disturbance factors, which include symptoms shared by both disorders.

The Zung scale was not useful because the data were inconsistent and the grossly psychotic state of the patients made it impossible to obtain baseline scores.

Depression was most marked at baseline and improved over time after administration of the two drugs. The 1 previously described exception was a patient who experienced substantial depressive symptoms after his schizophrenic symptoms remitted but whose depressive symptoms subsided and were unremarkable by the end of the study.

DeAlarcon and Carney (12) recently reported that 16 of their patients originally diagnosed as schizophrenic developed depression (including 5 suicides) after treatment with depot fluphenazines, which suggested that these drugs might be depressogenic. With the exception of the 1 case noted previously, our data indicate that depot fluphenazines are *not* depressogenic and in fact may have an antidepressant effect in acutely decompensated schizophrenic patients. However, the reduction in depression may be explicable by factors other than an antidepressant effect of neuroleptic medication. First, correction of the cognitive disturbance by the neuroleptic agent could reduce the depression by giving the patient greater cognitive control. This hypothesis is supported by numerous carefully monitored studies which show that the clinical action of neuroleptics is predominantly correction of the thought disturbance and not reduction in anxiety (13). Second, the placebo effect and therapeutic value of being a participant in a research project could be depressolytic.

The association of depression with schizophrenic decompensation is not surprising. Schizophrenia is a subjectively frightening and severely disabling illness. It is therefore not surprising that the schizophrenic individual would suffer from depression. Levin (14) contends that there is a depressive core in all schizophrenic patients. With the breakdown of cognitive control and defenses (e.g., denial) during decompensation, affects (including depression) become prominent and subside only when the patient regains cognitive control during reintegration. Our data, however, indicate that 40% of the schizophrenic patients had no depression despite acute decompensation and loss of cognitive control. Thus, a depressive core does not seem to be universal in schizophrenic patients in the reintegration phase.

Depression in schizophrenia is frequently considered secondary or reactive and thus analogous to depression in individuals with serious or distressing medical disorders. Recently, Akiskal and McKinney (15) reviewed the various theories of the origin of depression and stressed the collating role of the diencephalon in integrating the various depressogenic determinants, with a resultant clinical depression. Thus, there may be multiple biologic, psychological, and environmental determinants. It is not now known how these determinants vary in individuals who have primary affective disorders and those who have depression within schizophrenia. We also do not know whether schizophrenic patients who experience depression during decompensation and those who do not represent two distinct subgroups of the illness.

Postpsychotic State, Convalescent Environment, and Therapeutic Relationship in Schizophrenic Outcome

BY LAWRENCE KAYTON, M.D., JUDITH BECK, R.N., AND SOON D. KOH, PH.D.

The authors evaluated the following variables in the 2–3-year outcomes of 30 schizophrenic patients: the acute/chronic dichotomy, the presence of a postpsychotic regressive state, the quality of the convalescent environment, and the formation of a therapeutic relationship. They found that the presence of a postpsychotic regressive state was not associated with either good or poor short-term outcome; that the diagnosis of acute schizophrenia was almost invariably followed by good outcome, but a diagnosis of chronic schizophrenia had little predictive value; and that a favorable convalescent environment and the presence of a therapeutic relationship were significantly associated with good outcome.

THIS STUDY was undertaken to determine the relative influence of several distinct variables on the short-term outcome of young adult schizophrenia. In the past, there have been attempts to correlate an almost endless variety of factors with good and poor prognosis. Individual features that have been identified as having some enduring validity for good outcome include premorbid social adjustment (1, 2), acute onset (3, 4), confusion (5, 6), the presence of guilt (7), evident manic and/or depressive features (8, 9), and family history of clinical depression (9, 10). Although each of these factors has limited value as a predictor, their predictive ability increases to approximately 80% when they are combined, as Vaillant (10) and Stephens and associates (11) have shown. However, alone and collectively, these features all underlie a common developmental presumption, namely, that the age-appropriate development of affect, interpersonal relations, and individuation correlates positively with good outcome. Unfortunately, this tells us little more than we already knew. People who were more severely impaired before an overt decompensation are less likely by definition to have a good outcome, even if they recover to their status quo ante. It also has limited usefulness for influencing outcome because it presumes that outcome is, in a sense, preordained, i.e., that the natural course is intrinsic to the illness.

Statistical investigations focused on the psychotherapy of schizophrenia have of necessity minimized this intrinsic outcome perspective. In these studies therapeutic interventions are observed in reference to a specific outcome measure, such as one or more of the following: relapse of psychosis, rehospitalization, vocational functioning, social adaptation, and severity of symptoms. Most studies have clearly supported the effectiveness of chemotherapy in most facets of good outcome (12–17). In light of the almost incontestable therapeutic efficacy of neuroleptics in the treatment of most schizophrenic patients, it is important to determine what factors other than the neuroleptics and premorbid developmental level contribute to a better outcome.

This paper focuses on several other concomitant influences, namely, the presence of a postpsychotic regressive state, the quality of the convalescent environment, and the presence of a therapeutic relationship. We were also interested in seeing how effectively the acute/chronic dichotomy would correlate with outcome.

In a previous paper (18) one of us noted that a postpsychotic state characterized by such manifestations as passivity, neurasthenia, thought scattering or clogging, affective blockade, and, often, depression succeeded the psychotic episode in 13 schizophrenic young adults who had good outcomes. The therapeutic efficacy of resolution of this postpsychotic state was postulated to be a crucial factor for an enduring good outcome.

Schizophrenia surely does not end with the remission of the psychosis. Further recovery, if it is to take place, does so in a particular social context. Therefore, we attempted to assess the effects of the convalescent environment on outcome.

Although it is a well-established clinical maxim that the therapeutic relationship itself is the crucial ingredient in the therapy of schizophrenia, little system-

At the time this work was done the authors were all with the Psychosomatic and Psychiatric Institute, Michael Reese Medical Center, Chicago, Ill. Dr. Kayton was Director of Training, Ms. Beck is Director of Clinical Nursing, and Dr. Koh is Director, Laboratory for Perception and Cognition. Dr. Kayton is now Senior Consultant to the Illinois State Psychiatric Institute, Chicago, Ill., and Director of Psychiatric Research, Hines Veterans Administration Hospital, Hines, Ill. 60141.

This research is part of an extensive program investigating schizophrenia that is being conducted jointly by the Department of Psychiatry, Psychosomatic and Psychiatric Institute, Michael Reese Hospital and Medical Center; Pritzker School of Medicine, University of Chicago; and the Illinois State Psychiatric Institute. This research is supported in part by Alcohol, Drug Abuse, and Mental Health Administration grants MH-18991 and MH-19477 from the National Institute of Mental Health and by grants 131-13RD and 218-12RD from the State of Illinois.

atic work has been done in this area. In their comprehensive examination of therapeutic process in schizophrenia, Rogers and associates (19) concluded that the actual relationship with the therapist was more pivotal for schizophrenic patients than for psychoneurotic control patients. Unconditional positive regard and congruence were more important than accurate empathy to the schizophrenic patients. In our study, therefore, we were interested to see if the presence or absence of a therapeutic relationship affected outcome.

The fact that this is a preliminary study should be clearly noted at the outset of this report. Because of the small numbers of patients followed so far, any conclusions will, of necessity, be tentative. However, it is hoped that even with these small numbers and the limited length of follow-up we can begin to clarify some clinical aspects in the outcome of overt schizophrenic illness.

METHOD

The 30 young adults we studied had been admitted to the Psychosomatic and Psychiatric Institute of the Michael Reese Medical Center. They ranged in age from 16 to 36. Each patient was interviewed by a senior psychiatrist after informed consent was obtained. Each tape-recorded interview was rated on a number of variables, after which a diagnosis was made by the consensus of at least two members of the research team. The specific methods are detailed in a previous study by Grinker and Holzman (20). Cognitive studies, vestibular testing, eye scanning, psychological testing, family studies, and behavioral ratings were also conducted on many of the young adults interviewed and diagnosed.

A follow-up questionnaire specifically designed for this study has been sent to each patient annually after his or her discharge. This questionnaire can be given an outcome score using the Strauss-Carpenter Scale (21), which measures social and vocational adjustment as well as frequency of symptoms and rehospitalizations. Strauss and Carpenter found that a score of approximately 13 corresponded to the average outcome of neurotic patients, whereas a score of 11 corresponded to the average outcome for schizophrenic patients. Furthermore, a recent scoring of 24 normal control subjects from a local university yielded scores between 12 and 15, with a mean score of 13.9. Therefore, in this study we have considered good outcome to be a Strauss-Carpenter score of 12–16 and poor outcome to be any score below 12.

Chronic schizophrenia was diagnosed in accordance with the Grinker-Holzman criteria (20) and defined as a long-standing experience of inner turmoil and social incompetence with clear psychotic symptoms but without the appearance of an acute psychosis. A gradually developing psychosis is the usual picture. Acute schizophrenia was diagnosed when there was a sharp, rather sudden appearance of a psychotic episode after a period of good adjustment. For purposes of this study, we were interested only in the acute/chronic dichotomy and therefore eliminated such associated features as catatonia and paranoia.

The presence or absence of a postpsychotic regressive state, the nature of the convalescent environment, and the presence or absence of a therapeutic relationship was determined by consensus between two of us (L. K. and S. D. K.); we both had continued contact with each patient during hospitalization. Nursing notes, discharge summary, and progress notes were also used. Strauss-Carpenter outcome scores were compiled independently and were not available until all other data were recorded. The features that define a postpsychotic regressive state are contained in appendix 1.

A convalescent environment was rated as unfavorable if any one of the following features was present: the environment required or promoted the continued helplessness of the patient; the environment did not interdict unnecessary helplessness and passivity; the environment overtly or covertly rejected the patient and increased his or her sense of social estrangement; or the patient lived alone prematurely or in an impersonal environment without an adequate system of external supports (this situation might obtain through life circumstances, as in the case of parent death, through an avoidance of a more clearly pathological environment, or through the patient's overestimation of internal resources). A convalescent environment was rated as favorable if it provided a continuing feeling of safety without hampering individuation; thus, the environment could range from benign, passive, and supportive to more flexible, actively supportive, and accurately empathic. In this conception, a variety of environments could be construed as favorable if the parents, peers, or spouse of the patient provided nonintrusive emotional support through their attitude toward the patient and through sensitively timed interpersonal contact.

A therapeutic relationship was considered to be present if there was a positive emotional engagement by patient and therapist in the context of help-giving. Auxiliary clinical observations of a therapeutic relationship were consistent negative reactions to therapist absences and continuous positive emotional response when the therapist was present. Further support for a therapeutic relationship included voluntary continuation of therapy after discharge, the simple voicing of a good relationship by the patient, and the retrospective evaluation of the patient on follow-up.

RESULTS

The characteristics of the patient sample are presented in table 1. There were 15 chronic schizophrenic patients—5 women and 10 men. The acute schizophrenic population also consisted of 5 women and 10 men. The overrepresentation of men in this sample is not clearly understood; it may simply be an artifact.

TABLE 1
Characteristics of the Schizophrenic Sample

*Low scores (below 18) indicate good premorbid adjustment; high scores (18 or above) indicate poor premorbid adjustment.
**A score of 12–16 indicates good outcome; a score below 12 indicates poor outcome.
***All Strauss-Carpenter outcome ratings were made 2 years after hospital discharge except these, which were made 3 years after hospital discharge.

In the larger investigation, initial interviews of 264 patients have yielded an even distribution of men and women.

The premorbid social adjustment score on the Phillips Scale (22) indicated that the acute schizophrenic patients clearly had a better premorbid social adjustment. However, there were 4 chronic schizophrenic patients with a good premorbid social adjustment, and there were 6 acute schizophrenic patients with elevated scale scores. Although low Phillips scores (indicating good premorbid adjustment) were almost invariably associated with good outcome, only half of the poor premorbid scores reflected a poor outcome.

The postpsychotic regressive state was seen in 21 patients, including 11 with acute and 10 with chronic schizophrenia. There were 7 chronic patients with a postpsychotic regression who had good outcomes, whereas 2 out of 5 had a good outcome but did not have a postpsychotic regression. There were 3 chronic patients who had postpsychotic regressions and poor outcomes. Among the acute patients, 10 of 11 who had postpsychotic regressions had good outcomes, whereas 1 had a poor outcome. All 4 acute patients who did not experience a postpsychotic regressive state had good outcomes.

In this retrospective assessment of the postpsychotic regressive state, we found no relationship between the appearance of such a state and 2–3 year outcomes in this sample. However, further analysis of the data showed that the diagnosis, convalescent environment, and therapeutic relationship were all dependable predictors of outcome. The diagnosis of acute and chronic schizophrenia predicted the outcome fairly well. Fourteen of 15 acute schizophrenic patients had good outcomes regardless of their demographic and environmental circumstances (hit rate, 93%). However, among the chronic patients, 6 had poor outcomes and 9 had good outcomes, revealing a comparatively high false alarm rate (60%). The difference between the acute patients' mean score (13.07, SD=2.75) and the

chronic patients' mean score (11.53, SD=3.44) on the Strauss-Carpenter Scale was significant (t=2.05, df=28, p<.05). The biserial correlation computed between the scale scores and the acute versus chronic diagnosis was .45 (p<.05).

Eleven of 30 schizophrenic patients (8 were acute) had poor and 19 had favorable convalescent environments. The mean Strauss-Carpenter Scale score for the group with a favorable convalescent environment (14.6, SD=1.34) was much higher than that of the poor group (10.18, SD=4.12). The group difference was significant (t=3.91, df=28, p<.01). The biserial correlation between the scale scores and the two diagnostic groups was high (.74, p<.01). It was noted that in the chronic schizophrenic patients the outcomes were especially susceptible to the nature of the convalescent environment.

Finally, 22 schizophrenic patients developed a therapeutic relationship with the therapist. All but 1 acute schizophrenic patient had such a relationship; this individual went on to a good outcome. Of the 15 chronic schizophenic patients, 7 had no therapeutic relationship; 5 of these 7 went on to poor outcomes. The difference of the mean Strauss-Carpenter Scale scores between the good (13.64, SD=2.66) and poor (10.13, SD=3.60) therapeutic relationship groups was significant (t=2.91, df=28, p<.01). The biserial correlation was also substantial (.63, p<.01).

DISCUSSION

This study has assessed several variables in relation to outcome in schizophrenia. In previous papers (18, 23), the proper therapeutic management of a postpsychotic regressive state was postulated to be an important determinant for an enduring good outcome. Others have also postulated that the successful resolution of this clinical phenomenon bodes well for longer term outcome (24, 25). However, not all good outcomes studied by others have included such a state. Sachar and associates (26) described a "parasitic" followed by a "compliant" pathway to recovery and, in his review of the treatment of schizophrenia in the Soviet Union, Hein (27) named a hypersthenic remission that has a favorable vocational outcome.

Furthermore, the incidence of the postpsychotic state is not at all clear. Roth (28) considered this "depressed-neurasthenic" phase almost ubiquitous. Bowers and Astrachan (29) found a postpsychotic depression in over half of the 36 consecutive patients they studied. Stern and associates (30) reported 2 profound postpsychotic depressions and 6 moderate depressions in 17 schizophrenic patients in their sample. Finally, Sachar and associates found that "anaclitic depression" followed the disappearance of organized psychosis in all 4 intensively studied schizophrenic patients in one study (31) and 1 in 4 in a second study (26). Interestingly, no medication was used in either of these studies.

Because depression is a variable feature in this state, we prefer the term postpsychotic regressive state. In our study, 70% of 30 schizophrenic patients experienced a pronounced postpsychotic regression; thus, the incidence of this phenomenon is relatively high, ranging from 25% to 70%. It is found across cultures, in a variety of settings, and in different socioeconomic and racial groups; it appears with or without neuroleptic medication.

At this time we cannot make any definitive statements about the association of such a state with an enduring good outcome. We can conclude only that the postpsychotic regressive state is a frequent aftermath of schizophrenic disorganization. The presence of a postpsychotic regression seems to have no relationship to short-term outcome. However, the therapist remains in a clinical quandary when confronted with this phenomenon. This postpsychotic regressive state is resistant to ECT and tricyclic antidepressants (28, 29).

Four of the patients we studied had a postpsychotic regressive state followed by poor outcome. Of the 4, the 3 chronic schizophrenic patients had ego-syntonic regressions in which there was a continuation of overt thought disorder, conspicuous absence of insight into the nature and severity of their illness, and an inability to elicit and/or use the caretaking behaviors of helpgiving persons in the hospital. The 1 acute schizophrenic patient with a poor outcome had undergone a series of catastrophic episodes that preceded her acute schizophrenic episode. Because of this, she was unable to use caretaking behaviors in the hospital. Furthermore, she had a particularly unsatisfactory convalescent environment.

In summary, our findings suggest that there are two forms of the postpsychotic state: one is a true postpsychotic regression, and the other is an ongoing adaptation to a subdued, yet continuing, disorganizing process. In the true postpsychotic regressive state, sensitive caretaking with support of the regression is indicated, as detailed in previous papers (18, 22). Because this state spontaneously reverses, a graduated plan of social and later vocational mobilization can be instituted (23). In the subdued psychotic state, the therapeutic task is stabilization of the disorganizing process followed by an active rehabilitation program that sets realistically limited social and vocational goals. The support of regressive behaviors in this state should not be construed as potentially therapeutic, although it may become necessary in the event that rehabilitative efforts fail.

The diagnosis of acute schizophrenia is a very accurate predictor of good outcome; it predicted good outcome in all but 1 of 15 of our patients. This diagnosis can be made by interview either during or shortly after the psychosis. However, the diagnosis of chronic schizophrenia is a poor predictor of outcome 60% of our patients with this diagnosis had a good outcome, and 40% had a poor outcome.

The convalescent environment has been the subject of much study. Brown and associates (32) found that

former patients living with mothers or wives had higher readmission rates than those living with siblings, distant relatives, or in lodgings. Carstairs (33) found that success in remaining in the community was associated with greater welcome, the presence of a "key person," positive attitudes, and a perception of the patient as not dangerous. In an excellent review of the literature, Kreisman and Joy (34) concluded that a moderate to low level of emotional expressiveness, empathic understanding, and educated attitudes about mental illness are significantly related to good outcome. A composite of a therapeutic convalescent environment contained in their review paper corresponds closely to the favorable convalescent environment in our study.

In this investigation we used a concept of favorable convalescent environment as one that provides a continuing feeling of safety without hampering individuation. The definition provides an assessment in a variety of environments, whether the patient is living with spouse or parents, alone, with friends, or with other relatives. We found that the assessment of a favorable convalescent environment is an excellent predictor of good short-term outcome. This finding was especially prominent among patients diagnosed as having chronic schizophrenia. The finding has important clinical implications because a favorable convalescent environment can often be developed and perpetuated through a variety of clinical interventions.

Finally, we assessed the therapeutic relationship and found that a good therapeutic relationship is clearly associated with good outcome. There are obvious interactions between the presence of a therapeutic relationship and the presence of a good convalescent environment. On the one hand, parents, spouse, other relatives, or friends who compose important aspects of a good convalescent environment are more likely to support psychiatric treatment financially and attitudinally. On the other hand, a good therapeutic relationship can aid in the formation of a more favorable convalescent environment. Another interpretation of this finding is that schizophrenic patients with potentially better interpersonal relationships are more able to form therapeutic relationships; the formation of such a relationship may only be a measure of an intrinsically better outcome. However, many of the schizophrenic patients who developed a therapeutic relationship in this study were initially untrusting or even overtly interpersonally aversive. Therefore, we conclude that the *development* of a good therapeutic relationship appears to contribute to good outcome. Again, this finding is more striking in the chronic schizophrenic patients.

This study has focused on several aspects of the schizophrenic illness that may influence outcome. The postpsychotic regressive state, the nature of the convalescent environment, and the therapeutic relationship are all factors in which clinical intervention is possible. In this study, the latter two features were shown to clearly relate to good outcome. It is hoped that further studies will be directed to factors in the schizophrenic illness that may lead to beneficial modification.

APPENDIX 1
Characteristics of the Postpsychotic Regressive State

1. Abatement of the psychosis with some continuing internal disorganization.
2. Anergia and neurasthenia with behavioral quietude.
3. Early reversal of diurnal rhythm with excessive sleeping during the day. Later, falling asleep early in the evening and sleeping late in the morning. Afternoon napping common.
4. Early, may be food aversion with anorexia. Later, excessive food consumption, often with gorging and pronounced weight gain.
5. Staring and/or dysrhythmic eye blinking.
6. Thought clogging or thought scattering.
7. Desire to be alone.
8. Profound passivity.
9. Feelings of emptiness, aloneness, and unlovability.
10. Depression or total affective blockade.
11. Dyadic preoccupation.
12. Psychophysiological disturbances.
13. Transient exacerbations of disorganization in some patients, precipitated by specific stresses, such as separation from valued objects or firm expectations of independent functioning.

Strategies and Risks in Psychotherapy with Bilingual Patients: The Phenomenon of Language Independence

BY LUIS R. MARCOS, M.D., AND MURRAY ALPERT, PH.D.

The presence of two separate languages, each with its own lexical, syntactic, semantic, and ideational components, can complicate psychotherapy with proficient bilingual patients. If only one language is used in therapy, some aspects of the patient's emotional experience may be unavailable to treatment; if both languages are used, the patient may use language switching as a form of resistance to affectively charged material. The authors suggest that monolingual therapists should carefully assess the degree of language independence in bilinguals in order to minimize its impact on therapy. They conclude that study of bilingual patients may provide important insights into the nature of the therapeutic process.

BILINGUAL PATIENTS comprise an important proportion of the psychiatric population in many urban areas of this country. Although there is an abundant literature on bilingualism, its effects on the processes of psychotherapy have received limited attention.

Despite divergent views on many issues, writers on bilingualism concur that it has a major effect on personality formation and integration. While powerful sociolinguistic variables (e.g., migration, acculturation, and biculturalism) frequently covary with bilingualism and are well known for their tangible impact on the individual (1), the presence of two language systems that appear to be insulated from each other constitutes bilinguals' sui generis characteristic and is a fundamental factor affecting their lives. Understanding this impact requires appreciation of the phenomenon of language independence, that is, the bilingual's capacity to acquire and maintain two separate language codes—each with its own lexical, syntactic, phonetic, and ideational components—and to use them independently with minimal interaction. The bilingual operates parallel encoding mechanisms, each with its own stream of associations between message words and events in the ideational system. For example, for an English-Spanish bilingual the word *dog* will be linked to a certain stream of associations, connotative meanings, and idiosyncratic emotional experiences. For the same individual, the translation equivalent *perro* may well be identical in central denotative meaning; however, the associations, metaphorical extensions, and affective accompaniment may differ significantly.

The purpose of this paper is to examine the evidence for the phenomenon of language independence in bilinguals and to consider its functions and possible ways of operating during psychotherapy. Since verbal interaction is the instrument of psychotherapy, the existence of two evidently independent systems of language may be expected to modify fundamental aspects of the treatment process. The issues to be considered are especially relevant to dynamic psychotherapies that nurture self-knowledge, catharsis, and experiential insight.

The phenomenon of language independence is primarily applicable to proficient bilinguals, i.e., individuals who display native proficiency in each language, with minimal interference in speech production in either. Contrasted with the proficient bilingual is the subordinate bilingual, who shows a differential competence in two languages and uses translation equivalents when speaking in the second language. These individuals appear to possess a unitary semantic and ideational language structure (2). The implications for clinical psychiatry of this second group are different and have been the topic of previous reports (3–6). It is also important to distinguish between bilinguals who learned both languages in the same cultural context (compound bilinguals) from those whose languages had different acquisition contexts (coordinate bilinguals) (7, 8). Separation of language-acquisition contexts appears to enhance the functional independence of a bilingual's two languages (9–11).

EVIDENCE FOR LANGUAGE INDEPENDENCE

Aphasia

Compelling evidence for language independence comes from neurological studies of aphasia in bilinguals. Following cerebrovascular accidents or during deteriorating chronic organic brain syndromes, bilingual individuals exhibit differential impairment of their two languages (12–15). Recently a similar effect has

The authors are both with New York University Medical School, 550 First Ave., New York, N.Y. 10016, where Dr. Marcos is Assistant Professor of Psychiatry and Dr. Alpert is Professor of Psychiatry.

This paper was supported in part by Alcohol, Drug Abuse, and Mental Health Administration grant MH-08618 from the National Institute of Mental Health.

been reported in bilingual psychiatric patients after electroconvulsive therapy (16). Interpretations of these clinical observations vary and implicate a number of variables such as age at language acquisition, frequency of usage, and emotional attachment to the language. Most authors agree that the encoding and decoding mechanisms associated with a primary language have greater resistance to language pathology than do those associated with a secondary language. Neurologists have also formulated a theory of bilingualism (17, 18) and have hypothesized an anatomically localized language-switching control center in bilinguals. This hypothesis, if confirmed, may some day help us to understand individual differences among bilinguals with respect to the degree of language independence.

Psycholinguistics

Psycholinguistic investigators have repeatedly demonstrated empirically that bilingual subjects verbalize different associations in response to semantically identical words, according to the language in which the task is performed (19–22). In general, these studies suggest that words referring to concrete, high-imagery objects elicit more similar responses in the bilingual's two languages than do abstract words, which in turn tend to evoke more similar associations than words referring to feelings (23). Thus, for an English-Spanish proficient bilingual the words *table* and *mesa* may generate approximately the same mental representations; *freedom* and *libertad* will arouse different ones; and the words *love* and *amor* will mean and "feel" quite different. Ervin obtained strikingly different responses to the Thematic Apperception Test according to the language in which bilingual subjects were tested (24). The individuals participating were native speakers of French who were living in the United States and who spoke English fluently. Erwin found language-specific variations in the stories told and in the emotions expressed by these subjects. It appears that perception of role, recall, and projection of past experiences—three crucial aspects of the psychotherapeutic process—are affected by the language of report.

Findling studied the characterological traits "need affiliation" and "future orientation" in a group of English-Spanish bilinguals (25). Need affiliation was defined as the individual's concern over establishing, maintaining, and restoring positive relationships with others; future orientation, as the extent to which a person's preoccupation with events that may or may not happen precludes concern with events that have already taken place. The results demonstrated a language effect; both traits were significantly stronger when the subjects spoke English.

The Ervin and Findling studies (24, 25) permit one to infer that some proficient bilinguals have two linguistically confined personality structures. We will now examine the implications of this phenomenon for the process of psychotherapy.

IMPLICATIONS FOR PSYCHOTHERAPY

Although there is no evidence that monolingual psychotherapists are less effective in treating the bilingual patient, we know of no systematic study of this issue or of the effectiveness of treatment in the mother tongue compared with treatment in the second language that the patient acquired in youth, adolescence, or adulthood. However, the nature of the language independence phenomenon in itself, as well as the clinical material reported, suggests that a therapist who matches the bilingualism of the patient has special resources at his disposal. One purpose of this paper is to stimulate further discussion of this issue. We will consider the problems and opportunities specific to the psychotherapy of proficient bilinguals.

Unavailability

Unavailability refers to the presence of areas of the bilingual's intrapsychic world that remain hidden and unexplored due to the fact that they are independent of the language system in which the treatment is conducted. Because these areas are out of the therapist's reach, they cannot be part of the working material. The psychoanalytic literature reveals a number of examples illustrating this effect (26–31). Buxbaum (28) described the psychoanalysis of two German women who emigrated to the U.S. in adolescence. Both spoke German and English fluently, but English was the treatment language. One patient suffered from a severe preoccupation with the penis. During the course of treatment she frequently associated about the word *sausages*, but no therapeutic consequences resulted. Translation of that word into its German equivalent, *Blutwurst*, released from repression a series of memories that helped to uncover fundamental sexual material from her infantile years. Although the other patient had dreamed repeatedly in the course of treatment about *windows*, she gave no association to them; when the word was translated into the German *Fenster*, she verbalized a chain of relevant associations. Buxbaum concluded that, for these two bilingual patients, speaking in English meant avoiding the language of their key fantasies and memories, enabling them to detach themselves from significant psychic traumata.

Greenson (29) described the psychoanalytic treatment of a bilingual woman whose languages were German and English. Although the patient had used both languages during the first part of her treatment, she reached a point at which she totally refused to speak in German, claiming "I have the feeling that talking in German I shall have to remember something I wanted to forget." She was also afraid of saying obscene words in German; she felt that "they were much easier to say and much cleaner in English." Furthermore, the patient described herself differently in each language: "in German I am a scared dirty child, in English I am a nervous refined woman." From this experience, Greenson inferred that for this patient German was a pregenital tongue and the bearer of important unre-

solved conflicts. English, on the other hand, offered the patient an opportunity to build up a defensive system against her infantile life. The use of German during therapy was a technique designed to break through the strong defenses that isolated old structures from newer ones, which made possible the final resolution of the patient's neurosis.

Unavailability need not be an all-or-none phenomenon, and the consequences of relative unaccessibility of material will depend on the relevance of lacunae for particular treatment goals. It is reasonable to suppose, however, that if the lacunae are extensive or crucially placed the treatment may be incomplete or unsuccessful. Although unavailability may affect historical events, thoughts, images, and other levels of the personality structure, it will probably affect most often the integration of affective reactions to specific events and the freedom and direction of associational pathways.

Splitting

An alternate expression of unavailability may be deflection of the emotional component of a verbalized idea or experience. For example, the patient may report emotionally provocative material without expressing the expected concomitant affect. Krapf (30), in a clinical report about the choice of language in polyglot psychoanalysis, described the treatment of an English-Spanish bilingual who suffered from voyeurism. Although the treatment was conducted mostly in English, the patient spoke Spanish whenever he talked about his sexual activities. It became evident that this highly anxiety-provoking material could only be verbalized in Spanish because overwhelming anxiety accompanied its verbalization in English. Similarly, in a recent discussion of the defensive aspects of patients' lying during psychotherapy, Marcos (32) reported the case of a bilingual patient who, for more than one year, lied about fundamental aspects of her personality. The patient's languages were English and Spanish, but she always preferred to speak in English. As she began to speak Spanish her defensive lying became apparent, and an increase in her anxiety level took place. Marcos concluded that this patient chose the language that was less likely to provoke anxiety and, conversely, more likely to protect the ego against anxiety caused by the superego. Finally, Lukianowicz (33) studied the phenomenon of bilingual auditory hallucinations in polyglot psychiatric patients. His conclusions indicated that psychotic bilingual patients most often hear aggressive and threatening voices in their second language, whereas the "good" and protective voices use their native tongue. He suggested that this phenomenon represents a psychological defense mechanism that allows the hallucinating patient to dismiss his aggressive voices by "refusing to understand them."

The problems of unavailability and splitting may be reduced if the psychotherapist is careful to estimate the potential for noncongruence of the two language systems. Factors that should be routinely explored include the age and developmental stage of the patient when the languages were acquired, experiential sorting of language contexts and nature of the object relationships associated with them, and attitudes and values connected with each language. The therapist ought to explore and look for aspects that are shared by the two languages as well as events that seem unique to either one. This language evaluation will permit the therapist to assess the degree of language independence and to anticipate areas that may be unavailable in a particular language (34). Furthermore, once these factors have been identified, the therapist will be in a position to consider possible consequences of language independence in regard to the patient's specific treatment goals, as well as to plan therapeutic strategies to minimize the effects of this linguistic phenomenon.

Resistance and Facilitation

When the patient and the psychotherapist are matched bilinguals and the treatment is open to the use of either language, the patient's choice of language and the points of language switching become relevant to the psychotherapeutic process. Language switching may have either inhibitory or facilitatory effects, but it mainly offers the bilingual opportunities for resistance denied to the monolingual patient. If verbalizing experiences in the language in which they occurred renders them more real, the patient may choose to speak in the more abstract detached language to avoid anxiety. Although this capacity to modulate the emotional impact of associational material might on occasion be useful (e.g., when the superego concomitant with one of the languages is so strict that the patient may constructively choose to approach conflicting material through the less punitive language system), for the most part free use of language switching makes the course of treatment especially vulnerable to repression, compartmentalization, and denial. Until these issues are well in hand it might not be advisable to exploit the use of language switching as a therapeutic facilitator.

Technically, language choice and switching should be used by the therapist to explore areas of the bilingual patient's personality that are language specific. At a more theoretical level, however, language switching may be utilized strategically according to specific diagnostic features of the patient. For instance, it may be advisable to encourage an obsessive patient who uses constant intellectualization and avoidance to verbalize in his first, more emotionally charged, language. Conversely, a hysterical patient whose intense affect interferes with attempts at objectifying issues may benefit from encoding experiences in the second, less emotional, language.

CONCLUSIONS

We have summarized the evidence supporting the existence and delimiting the characteristics of lan-

guage independence in proficient bilinguals. This phenomenon has such practical importance for the psychotherapy of bilinguals that the prognosis for successful outcome may depend upon the language of treatment and the strategic handling of the two-language system. Therapists treating bilingual patients are confronted with special consequences of the language independence phenomenon. Unavailability of relevant material and splitting or lack of integration of associations and affects may give rise to misconceptions about the patient. When the treatment is conducted by a matched bilingual therapist, language switching strategies offer special technical resources, with theoretical implications for the treatment of different diagnostic categories of bilinguals. When the therapist is monolingual, language independence will still affect the treatment process; we have suggested language assessment methods to help the therapist minimize the obstructing effects of this phenomenon.

Study of bilingual patients may provide unique opportunities for gaining insight into therapeutic processes. Thus the language independence phenomenon may permit us to distinguish motivated repression from information retrieval failures due to encoding process factors. Furthermore, since proficient bilinguals may be conceived of as having duplex symbolic representation, they offer special possibilities for the study of relations among language acquisition, symbol formation, encoding mechanisms, and other cognitive processes currently thought to be essential to our understanding of psychotherapy.

Social Rehabilitation of Separation-Induced Depressive Disorders in Monkeys

BY STEPHEN J. SUOMI, PH.D., ROBERTA DELIZIO, AND HARRY F. HARLOW, PH.D.

The authors studied a group of four monkeys reared together, repeatedly separated from each other, and then exposed to another group of four monkeys reared in surrogate-peer groups who acted as therapists. The study group was compared with the therapist monkeys, a group exposed to the same separations but not to the therapist monkeys, a control group that experienced no separations, and two additional groups of stimulus animals. The authors' findings indicate that monkeys showing depressive behaviors after repeated separations can be returned to age-appropriate social performance through repeated exposure to socially active age-mates.

DURING THE PAST DECADE, numerous researchers working at several different laboratories have produced and studied depressive-like behavior in nonhuman primates. The rationale underlying this research has been twofold. First, our knowledge concerning depression is limited, and the ethical and practical constraints on research directly involving human patients are considerable; therefore, animal models of the disorder are sorely needed. Primates are probably the most appropriate subjects for such animal models (1, 2). Second, it is commonly assumed that "normal" behavior can be better understood when viewed in the context of abnormal behavior, particularly when the latter's origin is known. Consequently, several investigators have studied experimentally induced psychopathology in monkeys in order to understand more fully the process of normative socialization (3).

Most of the primate research involving induced depressive phenomena has used rhesus monkeys and other macaques in studies of mother-infant separation. This work has been based in part on the reports by Spitz (4), Bowlby (5), and others of human anaclitic depression resulting from infant separation from the mother. Several investigators (6–8) have successfully produced similar depressive behaviors, i.e., protest-despair reactions, in young monkeys by separating them from their mothers for prolonged periods of time. However, the monkey mother-infant separation paradigm has several major drawbacks as a general model for human depression. First, anaclitic depression is usually limited to infants, but mother-infant separation is hardly the primary cause of most adult human depressions. Second, recent research (9) has indicated that there is great variability in the response of infant monkeys to separation from the mother, just as there is for human infants; therefore, the procedure is not a reliable way to produce a population of depressed simian subjects.

An effective alternative procedure for production of monkey psychopathology involves peer separation. When performed under appropriate conditions, peer separations produce clear-cut depressive-like behaviors more consistently across a wider age range of subjects than do maternal separations (10). Further, the procedure is more flexible. It can be repeated a number of times on the same subjects, yielding depressive reactions in each case, and it requires fewer caretaking personnel. Peer separation is therefore more amenable to experimental manipulation than is maternal separation—at least in macaque subjects. Consequently, several recent studies of monkey psychopathology have employed peer separations to precipitate the desired disorders.

For example, Suomi and associates (11) reared infant monkeys without their mothers in groups of four from birth. From 3 to 9 months of age the infants were subjected to a series of 20 repetitive, short-term peer separations, each of 4 days' duration. The monkeys responded to each separation with protest-despair reactions, initially showing high levels of vocalizations and hyperactivity, which soon changed to depressive behaviors such as self-clasping, huddling, passivity, and social withdrawal. The monkeys did not adapt to the separations; the reactions they exhibited in the final separations were as pronounced as those exhibited during the first separations. Further, they developed maturational arrest as a cumulative reaction to the separation procedure. The basic manipulations of Suomi

and associates' study have been replicated a number of times, and the results have generally been consistent with the original findings. This technique can therefore be considered to be a reliable procedure for production of depressive-like phenomena in young nonhuman primates.

Once a satisfactory standard technique for production of a given form of psychopathology has been developed, it can then be employed to test the efficacy of specific therapeutic procedures. This stage has been reached with respect to monkey depressive behavior produced by peer separation. Consequently, during the past 2 years several researches designed to reverse such monkey disorders have been initiated at the Wisconsin Primate Laboratory. Some of these studies have used human antidepressant drugs such as imipramine (12), and others have used ECT (13). The data we will present in this report deal with a third approach—that of using other monkeys as "therapists" for our depressed subjects.

Conspecific therapists have been previously used to reverse other laboratory-induced psychopathologies in monkey subjects. For example, we demonstrated that the total isolation syndrome, i.e., psychopathology produced by rearing monkeys in social isolation for at least the first 6 months of life, can be almost completely eliminated by exposing the isolates to 3-month-old socially normal monkey "therapists" (14, 15). These therapists are effective because the behaviors they exhibit at 3 months—excessive social clinging, primitive play, and absence of aggression—are precisely the social stimuli that monkeys raised in social isolation need to overcome their social learning deficits.

It has always been our position that choice of a particular therapist should be entirely dependent on the behavioral dysfunction shown by the "patient" monkey. A total isolate monkey typically exhibits excessive self-directed stereotypy and an absence of even the most primitive social interchange. A normal 3-month-old monkey will readily cling to such an isolate, making it impossible for the isolate to engage in most self-directed behaviors. At the same time the younger animal can "teach" the isolate that social contact is comforting and desirable rather than frightening and otherwise noxious. The isolate is then amenable to development of an acceptable social repertoire parallel to the ongoing normal development of its therapist.

However, monkey depression represents a syndrome quite different from that of the social isolate. Most separated monkeys predominantly display inactivity and social withdrawal; the social behaviors that they do exhibit tend to be infantile and basically passive in nature. Thus a 3-month-old monkey who clings and is socially naïve would not necessarily be the most appropriate individual to elicit socially normal behavior. Instead, we reasoned that a stimulus monkey who could actively entice, even force, a separated subject out of its depressive social withdrawal would most likely be effective as a therapist. This proposition was tested in the following study.

METHOD

The general design of the study is outlined in tables 1 and 2. An experimental group of four rhesus monkey infants who had been reared together from birth were subjected to repeated peer separations in order to develop depressive behavior patterns (pretherapy phase). During a second series of repetitive separations they were exposed to the therapists, socially active stimulus animals equivalent in age to the experimental subjects (therapy phase). Later, they were subjected to a third series of peer separations, without interaction with the therapists (posttherapy phase). Finally, they were returned to interaction sessions with the therapists and were also exposed to two other groups of stimulus monkeys (subsequent interactions phase).

The experimental subjects were four rhesus monkeys (*Macaca mulatta*), two males and two females, who had been separated at birth from their mothers and reared as a group in a 6×4×6-ft pen for their first 3 months of life. Observational data were collected 5 days a week on each subject, beginning at 1 month of age. As in previous studies, these data consisted of durations of behaviors falling into 13 predefined categories, definitions of which are presented in appendix 1, recorded during the 7.5-minute period of each observational session.

Observational data were similarly recorded 5 days each week for the therapist stimulus animals. These were two male and two female monkeys comparable in age with the experimental subjects. However, they had been surrogate-peer reared (with inanimate cloth surrogate mothers and daily access to normal peers), a procedure previously shown to produce more socially active monkeys than the group-rearing procedure experienced by the experimental subjects (16).

Because of the form of the data collection, it was possible to compare data recorded for the subject and therapist monkeys during the pretherapy and therapy periods of the study with previously published data from two other groups of four monkeys (11, 17). Members of the first group (separation group) were reared in a manner identical to that of the experimental subjects and were subjected to the same separation schedule but were not exposed to any therapists (11). The other monkeys provided a nonseparated control group; they had been reared in a group but had not been subjected to separations of any form during their first year of life (17).

In the final phase of the study, both subject and therapist monkeys were exposed to two other groups of stimulus monkeys. The first consisted of four monkeys reared for the first 12 months of life in total social isolation and given chronic diazepam (Valium) treatment. Previous testing had shown these isolated monkeys to be socially inept. The other group of stimulus animals was composed of monkeys who had been reared from birth in nuclear families (for a complete description of the rearing environment see Harlow [18]). Previous

work had demonstrated that monkeys reared in nuclear families were probably the most socially sophisticated monkeys living in the laboratory (19, 20).

Data for the interaction sessions were collected in the same manner as described above. All of the data analyses to be discussed here involved repeated-measures analyses of variance of category means calculated for each subject over the specific time periods under question. When appropriate, the analyses were followed by Duncan tests between selected mean scores.[1] Statistical significance was defined as $p<.05$.

RESULTS

Pretherapy Phase

When the mean age of the group of experimental monkeys reached 90 days, a separation procedure identical to that used by Suomi and associates (11) was initiated. Each subject monkey was removed from the group pen and housed individually in a 2.5×2×2.5-ft cage, where it could see and hear but not contact other monkeys, for a 4-day period. After 3 days of reunion, a second 4-day separation was imposed, and after a second 3-day reunion, a third separation was imposed. This procedure continued until the subject monkeys had completed 12 separations and reunions.

The reactions of these monkeys to the separation series were quite consistent with those recorded in previous studies of repetitive peer separation. They responded to each separation with protest-despair reactions, and, as can be seen in figures 1–4, by 6 months of age they showed higher levels of ventral cling and self-clasp and lower levels of locomotion and play and sex than nonseparated control monkeys (17). Their behavioral levels were comparable with those of the separated subjects in Suomi and associates' study (11). Thus the data indicated that before therapy subject monkeys were as depressed as subjects in previous definitive studies of monkey depression.

Therapy Phase

In keeping with the separation procedure of Suomi and associates' study (11), subject monkeys, beginning at 7 months of age, were subjected to a second

[1]Complete results of all statistical analyses can be obtained from the authors on request.

Duration of Ventral Cling of Four Groups of Monkeys, in Mean Number of Seconds Per Observation Session

series of weekly 4-day separations and 3-day reunions. Unlike the previous study, however, subject monkeys were exposed to the therapist stimulus animals as pairs (one subject with one therapist) for two 1-hour sessions during each separation and for two 1-hour sessions during each reunion period. As can be seen in fig-

FIGURE 3
Duration of Locomotion of Four Groups of Monkeys, in Mean Numbe of Seconds Per Observation Session

ures 1–4, therapist monkeys at 3 and 6 months were socially superior to subject monkeys as well as to separated and control monkeys of comparable age. Therapist monkeys showed significantly higher levels of locomotion and play and sex and lower levels of ventral cling.

Despite these baseline behavioral differences, during the first 2 weeks of interaction sessions the therapist animals initiated few social exchanges with subject monkeys. Because we thought such exchanges were important for improving the latter's social repertoires we changed the format for the interaction sessions, hoping to stimulate the social performance of the therapist monkeys. The sessions were moved from the subject monkeys' group cage to the therapist animals' home cages, they were increased in frequency to one a day, and they paired two therapist monkeys with each subject, instead of the one therapist monkey in the previous sessions. In all, the subject monkeys were subjected to 8 separations and reunions in this phase of the study, and during each separation and reunion they were exposed to the therapist animals.

The therapeutic effects of even the modified interaction sessions were mild at best. The subject monkeys' behavior during both separation and reunion periods improved slightly as the therapy interactions progressed. By the end of the separation series subject monkeys were exhibiting significantly lower levels o

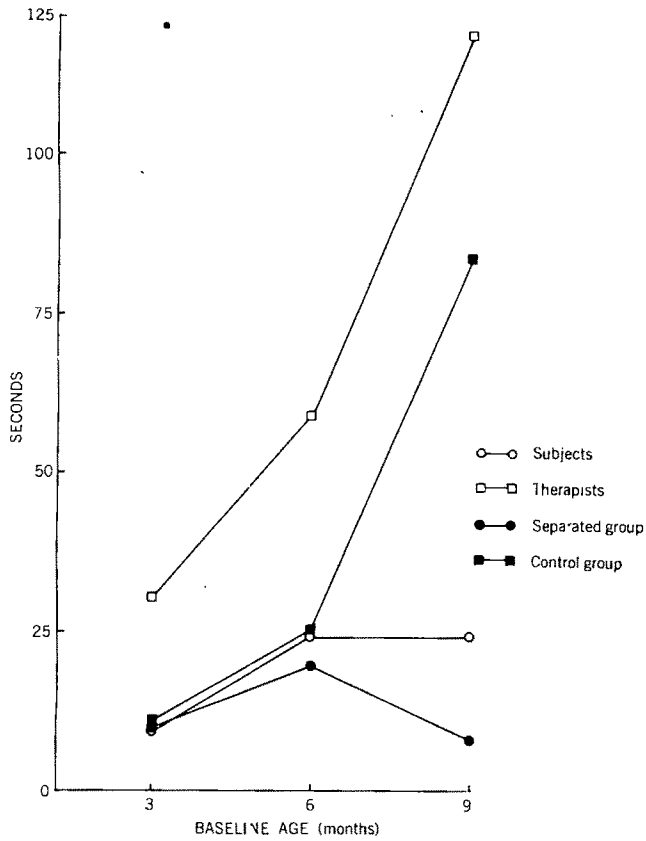

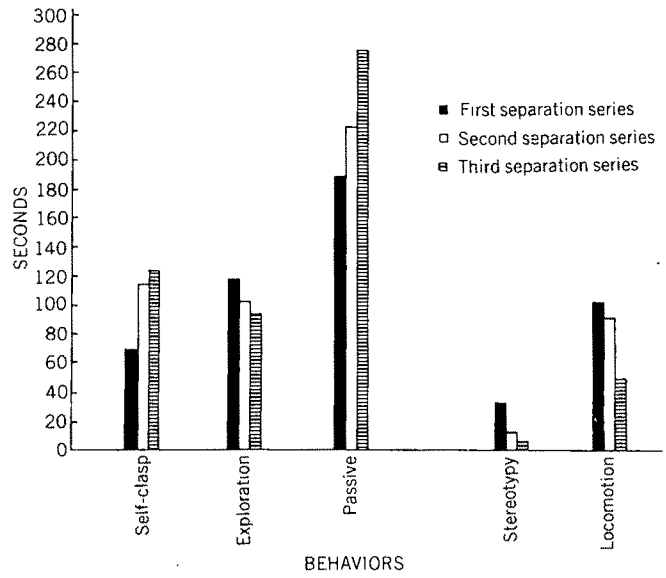

FIGURE 5
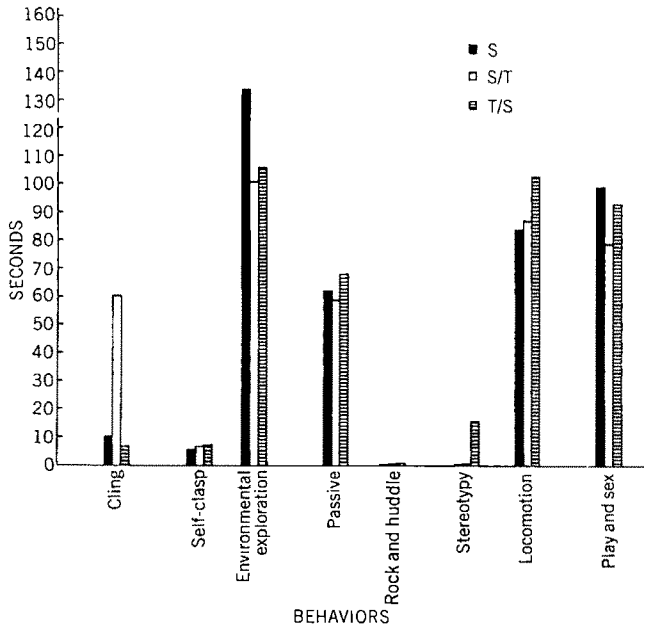
Duration of Various Behaviors of Subject Monkeys Averaged for Each Separation Series, in Mean Number of Seconds Per Observation Session

self-mouth, self-clasp, and ventral cling and higher levels of locomotion and play and sex than the separated monkeys, who had not had the benefit of therapy interactions. However, as is evident in the 9-month levels of figures 1–4, the subject monkeys were not socially equivalent to like-age monkeys who had not been separated. They showed higher levels of ventral cling and lower levels of locomotion and play and sex than the control monkeys and their own therapist animals.

Posttherapy Phase

In order to further assess any effects the above interactions may have had, the subject monkeys were subjected to a third series of separations from each other, beginning when their mean age was 12 months. A total of 8 weekly 4-day peer separations and reunions ensued. During this phase they were not permitted to interact with the therapist monkeys or with any other stimulus animals.

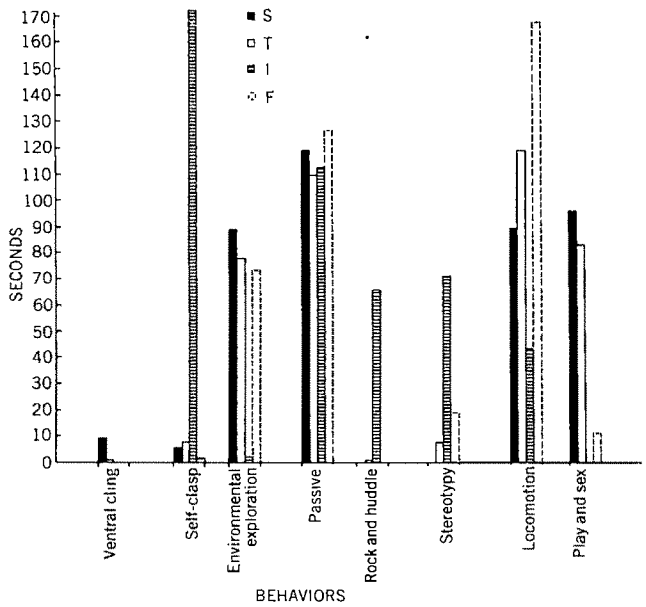
Figure 5 shows the mean levels for several behavioral categories during the third separation series along with comparable levels obtained from the first and second separation series. As can be seen in the figure, the experimental subjects actually deteriorated in the third separation series. These subjects showed significantly higher levels of passive behavior and lower levels of locomotion than during previous separations. Clearly, the experimental subjects remained debilitated by social separations.



Subsequent Interaction Sessions

In view of the subject monkeys' reactions to the third separation series, it was decided to initiate new interaction sessions with monkeys outside of their living group. At 14 months of age they were moved to a new group cage. Interaction sessions were run once a week in the subject monkeys' home cage, twice a week in their original group pen, and twice a week in a 12×10×8-ft social playroom in order to vary the physical surroundings to which the monkeys were exposed. At 17 months they were reintroduced to the therapist stimulus animals. Thereafter, as a group they interacted with all four therapist monkeys 1 hour a day 5 days a week for 12 consecutive weeks.

Levels of the subject group's behaviors during the interaction sessions were compared with those of the therapist monkeys during the same interactions and with the levels of their behaviors when interacting with each other. These results are summarized in figure 6. The analyses of variance revealed few significant differences between groups or types of interaction sessions. When interacting with therapist monkeys, the experimental subjects exhibited excessive ventral cling and relatively low levels of exploration and locomotion. Otherwise, however, they showed marked improvement over previously exhibited levels of most behaviors. Unfortunately, precise comparative data from the separated monkeys and the control monkeys were not available.



In order to test the generality of these improvements

FIGURE 6
Comparison of Duration of Various Behaviors of Three Groups of Monkeys Following Three Separation Series, in Mean Number of Seconds Per Observation Session*

in social activity, the subject monkeys were subsequently tested with two additional groups of similar-aged stimulus animals. First, beginning at 18 months of age, they were exposed to the group of isolated animals. The therapist monkeys were also exposed to the isolates. In 8 weeks of 1-hour playroom testing 4 days a week, isolated monkeys showed excessive self-clasp, rock and huddle, and stereotypy, minimal locomotion and exploration, and no play and sex. As in the previous interaction sessions, the subject monkeys exhibited levels of behavior comparable with those of the therapist group. These results are summarized in figure 7.

Finally, both the subject monkeys and members of the therapist group were exposed to the animals reared in nuclear families. The interactions took place in the social playroom in 1-hour sessions 2 days a week for both subject and therapist groups, for a total of 3 weeks. Some of the results of these interactions are also presented in figure 7. The formal analyses indicated that for levels of most behaviors the three groups of monkeys were statistically indistinguishable. Clearly, by 23 months of age the experimental subjects had achieved considerable recovery from the effects of the previous separations.

DISCUSSION

The present data indicate that monkeys exhibiting depressive behaviors following repetitive peer separations can be returned to age-appropriate social performance through repeated exposure to socially active age-mates. Of course, we do not claim that this procedure is the only way to alter depressive psychopathology in monkeys. It is entirely possible that certain antidepressant drugs or ECT could be equally or even more effective and/or more rapid in their mode of action. Current research at our laboratory suggests that this may indeed by the case (12, 13). We are not even convinced that the present research represents the most effective use of monkey peers as therapists. Given our choice, we would have rerun the study using more actively playful stimuls animals, perhaps 1–2 months older than those employed, and we would have increased the duration of the initial interaction sessions by at least three times that used in the present study. Clearly, we do not feel the procedure was optimal—only that it eventually worked.

We believe that the value of such research lies not only in the possible application of the therapy procedure itself, but also in the light it can shed on various monkey models of depression and other psychopathology. The development of techniques that reverse any disorder invariably adds to the overall understanding of the nature of that disorder. We plan to continue our researches using specific monkeys as therapists for disturbed subjects in order to answer the following questions:

Do procedures that reverse depressive reactions to

peer separation also reverse depressive behaviors produced by other manipulations, e.g., vertical chamber confinement or injection of pharmacological agents such as reserpine (21)? How do alternative somatic therapies such as imipramine or ECT compare with social approaches in terms of speed of reversal, presence of side effects, duration of treatment, and prevention of future occurrences of the disorder? Finally, can more effective therapeutic techniques be developed if one uses combinations of both social and somatic approaches? We feel that answers to such questions will greatly further our understanding of monkey depressive disorders. It is our hope that they will add to the understanding of human problems of mental health as well.

APPENDIX 1
Operational Definitions of Behavioral Categories

Ventral cling: contact of own ventral body surface with another object.

Self-clasp: clasping of any part of own body with hand(s) and/or foot (feet).

Self-mouth: oral contact with own body.

Environmental exploration: tactual and/or oral manipulation by subject of inanimate objects.

Rock and huddle: huddle accompanied by stereotypic rocking.

Aggression: vigorous and/or prolonged biting, hair pulling, and/or clasping, accompanied by one or more of threat, barking, piloerection, or strutting.

Passive: absence of all social, exploratory, and locomotor activity.

Stereotypy: identical movements maintained in a rhythmic and repetitive fashion for at least three cycles (scored independently and noninclusive of locomotion).

Locomotion: any self-induced change in location of subject.

Social contact: contact and/or proximity (within 2 in) with another subject.

Play and sex: any sexual advances or posturing directed toward another subject and/or any type of play activity (including contact and noncontact play).

Vocalization: any sound emitted by subject.

Huddle: self-enclosed, fetal-like position.

Patient Privacy and Confidentiality at Mental Health Centers

BY JOHN O. NOLL, PH.D., AND MARK J. HANLON, M.A.

The authors studied potential violations by mental health centers of individuals' rights to privacy and confidentiality by sending questionnaires to state directors of mental health programs and to mental health centers in all of the 50 United States and its territories. The questionnaires assessed the extent to which information that could identify a patient is reported to state offices; it also addressed issues of mental health center discretion in reporting information, patient consent to reporting information, the life span of patient files, and the access of outside agencies to mental health center files. The authors conclude that legislative action prohibiting the reporting of identifying information appears desirable.

THE ISSUE OF CONFIDENTIALITY is considered in the ethical codes developed by the American Medical Association (1), the National Association of Social Workers (2), and the American Psychological Association (3). All claim respect for the confidentiality of client or patient communications and, by implication, for the individual's right to the privacy of his or her contacts. Individual mental health professionals appear to differ in their interpretations of patient rights to confidentiality, and they may employ differing procedures regarding these rights. The manner in which this is done also seems to be contingent on the purpose and nature of the particular clinical interaction in which they are engaged and the source of reimbursement for their services (4–10).

PURPOSES OF SURVEY

In an earlier article (6) one of us (J.O.N.) discussed what he called the practice of "selective confidentiality" by mental health professionals. This term referred to the routine reporting of names and other information about patients by mental health centers to their state offices of mental health (or their equivalent) without the patient's knowledge or consent. As far as he could determine, this practice was prevalent.

To investigate the extent to which identifying information is routinely reported to central offices, a brief questionnaire was constructed and sent to all 54 active members of the National Association of State Mental Health Program Directors (11). These included directors in the 50 United States plus the District of Columbia, Guam, Puerto Rico, and the Virgin Islands. Forty-six completed surveys were returned in response to the first mailing. A follow-up request was made to the 8 states or territories that had not responded to the original mailing. In response to the follow-up mailing 1 additional state returned the questionnaire, increasing the total number to 47 for an 87% rate of return.

A very similar questionnaire was also sent to a sample of 210 comprehensive mental health centers representing all of the United States and its territories. The centers were obtained from the directory of comprehensive mental health centers (12). One hundred eighteen of the centers (56%) returned completed questionnaires, representing all but 2 states and 2 territories. Taken together, information was received either from the state director or from at least 1 mental health center in all 50 states plus the District of Columbia; 1 territory failed to respond at either level.

For our purposes the definition of potentially identifying information was limited to names, addresses, and Social Security numbers, although other categories of information were included on the questionnaire.

State directors of mental health programs and directors of mental health centers appeared to be interested in the issues of patient confidentiality and privacy. Ninety-six percent of the state directors and 95% of the mental health center directors who returned completed questionnaires requested the results of the survey. Furthermore, 68% of the state directors and 42% of the mental health centers reported that they were currently considering revisions of the kinds of information they either requested or submitted.

RESULTS

1. Nature and frequency of identifying information reported by mental health centers and received by state directors. The first question asked of the mental health centers was, "Which of the following items of information do you report to your state department of mental health or its equivalent about the individuals served by your center?" The responses were as follows: name, 30%; address, 31%; Social Security number, 25%; and one or more of the preceding, 51%.

The state directors were asked whether they re-

Dr. Noll is Professor and Director of the Clinical Training Program, and Mr. Hanlon is a graduate student in clinical psychology, Department of Psychology, University of North Dakota, Grand Forks, N.D. 58202.

TABLE 1
Responses of 47 State Directors to Question on Percentage of Agencies Reporting Potentially Identifying Information

Response	State Directors Who Checked Response	
	Number	Percent
Percentage of agencies reporting identifying information		
100%	10	21.0
80%–99%	4	8.5
60%–80%	1	2.0
40%–60%	4	8.5
20%–40%	4	8.5
1%–20%	5	11.0
None	12	25.5
No response	7	15.0

ceived these identifying data from mental health centers. Their responses were as follows: name, 28%; address, 34%; Social Security number, 23%; and one or more of the preceding, 66%.

The percentages reported by the state directors were comparable to those reported by the mental health centers.

The state directors were requested to respond to another comparable question: "What would you estimate to be the approximate percentage of reporting agencies who report information that could be potentially identifying of the individual served? (Those facilities that report one or more of the following items of information: name, address, Social Security number.)" Table 1 shows their responses to this question, which were very similar to the responses to the preceding one. Sixty percent of the state directors reported receiving one or more identifying types of information from the agencies in their respective states.

2. The extent to which informed consent practiced. To determine the extent to which individuals were informed or made aware that information about them might be sent to a state office, the following was asked of the mental health centers: "Are individuals advised that their names or other identifying information may be reported to the state office?"

The state directors were asked, "Are individuals advised that their names or other identifying information may be reported to your agency?"

Twenty-six percent of the mental health centers and 30% of the state directors said yes to this question, and 61% of the mental health centers and 15% of the state directors said no. Thirty-eight percent of the directors said that they did not know, and 13% of the centers and 17% of the directors did not respond to the question.

It is important to note that the figure of 61% for negative responses of mental health centers is an inflated one because this response category was chosen by mental health centers that had policies restricting the reporting of identifying information. To be consistent with their responses to the first question, they should not have responded to this one.

To clarify these responses, both questions were analyzed together. A tally was made of mental health centers that indicated they routinely reported identifying information on the first question and that responded to the no category on the later question. These results revealed that 36% of the mental health centers that acknowledged reporting identifying information *did not inform their patients that they did so.*

Both questionnaires inquired into the possibility that a patient could refuse permission to report identifying information and still obtain services. The question was, "If so, are individuals permitted to refuse permission for this and still obtain services?" Thirty-four percent of the mental health centers and 34% of the state directors said yes; 9% of the centers and 6% of the directors said no; 19% of the directors said they did not know; and 57% of the centers and 40% of the directors did not answer the question.

The large percentages of no response were to be anticipated because response to this question was contingent on the response to the preceding one.

Discussion. The extent to which identifying information was reported is somewhat surprising in view of the growing concern over patient rights to privacy. Reporting of this nature appears to be contrary to the ethical stance of all three major mental health professions, especially if the information is provided without the patient's full and informed consent (7).

We believe that it is reflective of the sensitivity to these issues, and perhaps of a lack of knowledge of the practices at the local mental health center level, that 38% of the state directors said they did not know whether the patient was advised that information was reported to the state. Thirty-six percent of the mental health centers acknowledged that the patient was not informed. Although this is possibly an underestimate, it indicates that although reporting identifying information remains a prevalent practice, it is not so widespread a phenomenon as has been alleged (6). Inconsistencies regarding the amount of identifying information that was made available to state offices are to be noted.

3. The extent of discretion allowed mental health centers in reporting. Inquiry was made about the discretionary powers that the mental health centers might exercise over the reporting of identifying information, i.e., did the mental health center have the option to be selective about the information reported to the state?

The question was, "Is your facility allowed to use its own discretion in reporting certain items of information? (For example, you may not wish to report individual names, but may report Social Security numbers or you may report only demographic characteristics.)"

For the state directors the beginning part of this question was, "Are the reporting facilities allowed . . . ."

The replies were as follows: 58% of the mental health centers and 43% of the state directors said yes;

37% of the centers and 49% of the directors said no; and 5% of the centers and 8% of the directors did not answer the question.

We also inquired into the manner in which state reporting requirements were made known to mental health centers: "If you are allowed to use your own discretion, how were you made aware of this policy?" Nine percent of the mental health centers and 2% of the state directors said state law prohibited the reporting of identifying information; 23% of the centers and 36% of the directors said they knew of the policy through a central office bulletin; 12% of the centers and 9% of the directors said the reporting agencies asked about the policy and were told; 20% of the centers and 13% of the directors answered "other"; and 36% of the centers and 40% of the directors did not respond to the question.

Discussion. It was only when the individual mental health center questionnaires within a state were compared with each other and with the questionnaire of their state director that we became aware of the many contradictions in reporting and the differing reporting policies that existed within the several states.

In some instances mental health centers indicated that they were allowed no discretion in reporting but the state director of the same state indicated that the mental health centers had discretionary powers in deciding what if any identifying information to report. The centers within a single state might report mutually exclusive policies regarding reporting, some saying that they had discretion and others reporting they did not. At the same time the state director might reply that discretion was allowed.

Frequently, when discretion was permitted and the mental health centers were aware of their discretionary options, they reported all three basic identifying data: name, address, and Social Security number. Some states had two or more reporting systems, apparently depending on the source of financial support for the local center. Furthermore, a number of states indicated that there were different reporting procedures for the following categories: inpatient services, mental retardation services or care, mental hospital residence, drug and alcohol programs, and whether the individual was insured by a particular legislative program. In addition, a few centers reported taking a position against state office requirements to report identifying information.

4. Life span and confidentiality of patient records. The protection of patient confidentiality is also a function of the policy governing patients' files. The state directors were asked two questions about this issue.

The first was, "What are your policies regarding patient files or records at the local level?" Fifty-three percent of the directors stated that each facility decided this for itself; 21% advocated life spans for records ranging from 3 to 30 years (median of 6 years) after termination of services; 19% stated that indefinite storage of records was advocated; and 6% chose the response category "other."

The second question was, "What are your policies regarding patient records at the state level? (This would be the information provided to your office by the various reporting facilities.)" Twenty-six percent of the directors advocated life spans ranging from 6 months to 10 years (median of 4 years); 57% stated that records were kept indefinitely; 15% chose the response category "other"; and 2% did not answer the question.

The mental health centers were asked, "What are your policies regarding patient files or records?" Nine percent of the centers reported a range from 3 to 15 years after which they destroyed patient records or files (median of 10 years); 81% stated they stored records indefinitely; 8% chose the response category "other"; and 2% did not answer the question.

The most frequent policy governing patient records or files was to store them indefinitely, whether at the state or local level. A number of state directors indicated, however, that their records did not include identifying information. This would be consistent with states that reported policies not requiring identifying information.

Another aspect of privacy and confidentiality explored was the question of access of other agencies to mental health center files. We inquired of the centers, "Do other agencies have limited access to files of certain populations of clients? (Such as welfare agencies who may be paying for the service you are providing the client.)" Thirty-one percent of the centers said yes; 64% said no; and 4% did not answer.

The centers were then asked, "If yes, please list each agency below and indicate the type of information to which they do have access."

Written notes on questionnaires revealed a diversity of practices regarding third parties. Typically a signed consent form was required whether the respondent replied yes or no to this question. Some mental health centers routinely sent information to certain referral sources without obtaining the patient's signed consent but did not send information to other agencies or referral sources unless they had obtained consent. No mental health center mentioned a policy of no contact with third-party inquiries.

CONCLUSIONS

It appears that a complete examination of patient privacy is long overdue. The interest demonstrated by many of our respondents indicates their awareness that changes more in keeping with the protection of patient privacy should be made. In a few instances there was an expression of need to report more fully identifying information than had been reported in the past because of the "current emphasis on accountability" or because the state was planning to participate in the Multi-State Information System (13). These concerns are illustrative of the potential conflicts that may emerge when considering the value of protecting

the privacy rights of individuals as opposed to other competing values or demands, such as cost accountability, access to records for research purposes, and program evaluation.[1]

Perhaps the most disturbing piece of data obtained was that legislative protection of patient privacy that prohibits the reporting of name, address, or Social Security number apparently has been enacted in only 1 state, Connecticut. One state director indicated that legislation existed prohibiting the state-level office from requiring the reporting of the names of individuals from mental health centers, but the centers could and did voluntarily report such information. The same state requires mental health centers to report the addresses of individuals; reporting of Social Security numbers remains permissive.

It was surprising that 66% of the state directors reported that they received at least some identifying information from mental health centers. This and the fact that a large percentage (36%) of the centers did not inform their patients that this information was being reported about them raises serious questions about the routine violations of the privacy of thousands of individuals who apply for services at their local mental health centers throughout the United States and its territories. However, we would assume that a higher percentage of identifying information is actually being reported because of the competing reporting systems found in many states. Furthermore, there seems to be a growing reliance on Social Security numbers as more welfare funds are allocated for these services. The results also reveal contradictory reporting practices and policies, uncertainty about record keeping, differing practices regarding third-party inquiries concerning services rendered on behalf of third parties, and varying demands and expectations from differing policy-establishing groups.

If it is accepted that a person is entitled to privacy regarding contact with a mental health center (or a private practitioner, for that matter), the implementation of the concept of informed consent would appear to be a crucial consideration. Ultimately, a much more satisfactory step toward ensuring privacy would be legislative action prohibiting the reporting of identifying information to any state agency or to any other information-pooling agency. In light of the fact that legislative action is often a slow remedial device, implementation of policy at state and local levels probably would prove to be more expeditious.

The matter of patient records is another area begging for correction. We are constrained to ask why records are kept as if they were as valuable as gold coin collections. The potential violation of the individual's right to privacy and confidentiality is too great not to explore this area thoroughly.

[1]The Research and Evaluation Division of the New Mexico Department of Hospitals and Institutions has been considering a nonunique tracking system that offers one solution to these apparent dilemmas. This computerized system has a built-in error-in-identification rate that, although acceptable for research or cost-analysis purposes, is not acceptable for legal purposes or other official inquiry. Although this proposal was made for state office operation, it could conceivably be implemented at the mental health center or agency level as a replacement for individually identified files.

Patients' Perceptions of the Therapeutic Relationship and Group Therapy Outcome

BY ALAN S. GURMAN, PH.D., AND JAMES P. GUSTAFSON, M.D.

The authors review the empirical literature examining the hypothesized relationship between the patient's perception of the therapeutic relationship and treatment outcome in group therapy and describe studies of both inpatient and outpatient group therapy. Their review indicates that, in contrast to the overwhelming evidence in support of the perceived relationship-outcome hypothesis in individual psychotherapy, there is no persuasive evidence in favor of the proposed relationship between the therapist-patient relationship and the efficacy of group treatment. The authors discuss the clinical and theoretical differences between individual and group therapy that would contribute to this result.

ALL MAJOR SYSTEMS of psychotherapy have emphasized the importance of the therapist-patient relationship, although their explanatory languages for the centrality of the relationship construct clearly vary. Social psychological theories highlight the mediational role of the relationship in arguing that the patient's attraction to the therapist heightens the therapist's ability to influence the patient toward therapeutic ends (1–3). Social learning approaches emphasize the therapist's role in the relationship as that of a salient source for modeling and reinforcement of new patient behavior (4). The neoanalytic writings of Fromm-Reichmann (5), Menninger (6), and Sullivan (7) support the common observation that analytically oriented therapists view the resolution of the neurotic distortions of the relationship as the cornerstone of their work. More recently, Strupp (8) argued that the parent-child relationship established in dynamic psychotherapy is the key source of the therapist's influence.

The most emphatic statement of the necessity of a facilitative therapeutic relationship for positive personality change has been made by Rogers (9), who went so far as to argue for the sufficiency of the conditions of empathy, warmth, and genuineness for effective psychotherapy. Nearly two decades of research have now made it clear that such relationship dimensions are rarely sufficient for patient change in individual psychotherapy (10), but it seems difficult to impugn their necessity, at least as preconditions for change. The predominant mode of assessment of the therapeutic relationship has been the rating of tape-recorded therapy interactions by trained nonparticipant judges. Thus, as Howard and Orlinsky (11) noted, most research in this area has been misguided on theoretical grounds, in that Rogers stated unambiguously that the mere offering of therapeutic conditions to a patient is not sufficient for positive change (9). Rather, these attitudes or styles of relating must be communicated to the patient, i.e., the patient must perceive them for change to occur.

Evidence has also been adduced that tape-rated therapeutic conditions are generally predictive of patient change in group psychotherapy (12). The purpose of the present paper is to evaluate the empirical and theoretical status of Rogers' (9) perceived-conditions–outcome hypothesis in group therapy in light of the fact that data from research in this domain are clearly more consistent with the theoretical underpinnings of the relationship construct than are those based on the perceptions of external judges.

More than technical issues arise in applying Rogers' hypothesis to group therapy. Rogers himself suggested that in the group situation leader acceptance may be less important than acceptance and understanding from peers (13). Hence, the correlation of outcome with desired leader qualities may not yield significant results. Yalom's outcome study of outpatient group therapy (13) supports this idea: he found that popularity with other group members and cohesiveness of the group were the only two factors associated with good outcome. Even if we consider leader characteristics alone, it seems that the variables of empathy, warmth, and genuineness represent only a part of the necessary attributes of the successful group leader.

The study of encounter groups by Lieberman and associates (14) demonstrated that the successful leader must provide a clear cognitive framework for group members to be able to make good use of their affective experiences. Yalom (13) suggested that in a group the tripartite analogy to the good relationship of individual therapy is the patient's relationship to his group therapist, to the other group members, and to the group as a whole. That is, the relationship with the therapist is only one of the critical aspects of the group therapy interaction that can influence outcome.

A further difficulty with the client-centered hypothe-

Dr. Gurman is Assistant Professor and Director of the Outpatient Clinic, and Dr. Gustafson is Assistant Professor and Director of Group Therapy Training, Department of Psychiatry, University of Wisconsin Medical School, 427 Lorch St., Madison, Wis. 53706.

sis in group therapy is that many schools of group therapy systematically attempt to influence the group members through variables other than the leader's empathy, warmth, and genuineness. The obvious examples of this are schools of group therapy that emphasize a group-centered rather than a leader-centered approach. Yalom's technique, for example, although it also attempts to use the leader-patient relationship, relies heavily on the "social engineering" of the group situation. Another technique of this type is that recommended by Whitaker and Lieberman (15), which attempts to help the group find less restrictive solutions to its shared conflicts.

At the other end of the continuum are schools of group therapy that rely almost entirely on an intense pairing relationship between therapist and patient and use the group as a chorus. The outcomes of such leader-centered groups would seem to depend more heavily on the personal qualities of the leader and thus be more likely to confirm the client-centered hypothesis. Examples of this type are many Gestalt, transactional analysis, and psychoanalytic group therapies. Of course, most contemporary schools are both leader-centered and group-centered, at least in some aspects.

A clearly intermediate strategy is that recommended by Foulkes (16), in which the leader permits the group to be leader-centered in the beginning, gradually helping the group to shift toward a more democratic peer-oriented style as the group masters its relationship with the authority of the leader. Hence, in that kind of group we might expect to find the client-centered hypothesis confirmed in the early stages of the group but not in the later stages.

With these important reservations in mind, we examine the existing data that focus solely on the relationship between the patient's perception of therapist empathy, warmth, and genuineness and outcome in group therapy.

PATIENTS' PERCEPTIONS OF THE THERAPEUTIC RELATIONSHIP IN GROUP THERAPY

A summary of empirical studies of the perceived-therapeutic-conditions–outcome hypothesis in group therapy is presented in table 1. Only 11 studies testing the hypothesis in question have been conducted under actual treatment conditions, 6 with outpatients and 5 with inpatients. The patient's perception of the therapist-patient relationship was assessed by either the Relationship Inventory of Barrett-Lennard (RI) (28) or the Truax Relationship Questionnaire (22), both of which have been found to share a good deal of common factor variance (29).

Among the outpatient studies (17, 19–21, 27) only those of Truax and associates (27) and Hansen and associates (19) found even tenuous support for the proposed positive relationship between patient-perceived therapeutic conditions and outcome. In Truax and associates' study, of the 69 correlations computed between 23 change measures and therapist empathy, warmth, and genuineness, only 9 were statistically significant. Because 4 correlations would be expected to reach statistical significance ($p<.05$) on the basis of chance alone, the reported positive correlations appear to just minimally exceed this level and, at best, can be interpreted as providing only very weak evidence for the perceived-conditions–outcome hypothesis. All but 1 of these significant correlations were obtained on MMPI change measures, and only 1 of the 15 conditions—Q-sort correlations—was significant. In addition, the obtained significant correlations were quite low (range, .23–.31), and over a third of the correlations were of zero-order magnitude.

The first study by Hansen and associates (19) found a significant rank-order correlation (.83) between group members' perceptions of their group leader's therapeutic conditions and self-concept change based on a Q-sort. The authors' data analysis was based on the mean perceived conditions and mean self-concept change within each of their treatment groups, yielding an N of 6. The more appropriate statistical analysis, and the only one that would have allowed direct testing of the Rogerian hypothesis, would have involved Pearson's product-moment correlation of individual members' scores on these two measures. Unfortunately, therefore, the authors' inappropriate data analysis obscures the meaning of their finding and may explain why this result failed to be replicated in a later study by Hansen and associates (20), in which the appropriate correlational analysis was performed.

Further support of the lack of evidence for the perceived-conditions–outcome hypothesis in outpatient group therapy is derived from the overwhelmingly negative results obtained in the study with the soundest methodological quality (17). We used the raw data provided by these authors to compare composite overall change scores (positive versus negative) and RI scores (above and below the group median). We found nonsignificant differences according to chi-square analysis.

Studies testing the hypothesis in question with hospitalized patients report more mixed but also largely negative results. The study of hospitalized mental patients of Truax and associates (25) showed unequivocally negative results for the perceived-conditions–outcome hypothesis. Roback and Strassberg's results with severely disturbed patients (23) also failed to support the hypothesis.

More mixed results were obtained in two studies by Truax and associates, one conducted with hospitalized psychotic patients and institutionalized juvenile delinquents (24) and one conducted with institutionalized delinquents only (26). In the first of these studies (24), perceived unconditionality of regard and congruence but not empathy and level of regard were significantly related to a composite final outcome criterion (FOC), composed of 8 change indices. The clinical meaning of these positive correlations is largely obscured by the unfortunate inclusion of both behavioral and self-re-

TABLE 1
Summary of Studies of Patients' Perceptions of the Therapeutic Relationship and Treatment Outcome in Group Therapy

Study	Subjects	Average Number of Sessions	Outcome Criteria*	Principal Finding*
Abramowitz and Abramowitz (17)	26 college students (4 groups)	10	10 measures (e.g., self-esteem, anxiety, alienation, and internal control)	Perceived TH conditions not related to outcome in either insight or noninsight groups
Anderson and associates (18)	61 hospitalized acute patients, most with schizophrenic or depressive reactions (4 groups)	30	T and P global ratings of session satisfaction (120 total sessions)	TH understanding (E) and interest (R) related to satisfaction
Hansen and associates (19)	50 students in grades 8–12 (6 groups)	12	Self-concept	Mean (across groups) self-concept change and mean (across groups) perceived TH conditions significantly related
Hansen and associates (20)	70 students in grades 8–12 with school behavior problems (9 groups)	12	Self-concept change	Perceived TH conditions not related to outcome
Lindahl (21)**	22 undergraduate college students (4 groups)	20	FIRO-B discrepancy scores, real versus ideal self, social anxiety, Eysenck Personality Inventory	Perceived TH conditions related to some change measures, but generally no support for the hypothesis of relationship of conditions and change
Lindahl (21)**	34 undergraduate college students (7 groups)	30	FIRO-B discrepancy scores, real versus ideal self, social anxiety, Eysenck Personality Inventory	Perceived TH conditions related to some change measures, but generally no support for the hypothesis of relationship of conditions and change
Roback and Strassberg (23)	18 hospitalized schizophrenic patients (3 groups)	16–30	Behavioral (e.g., Wittenborn scales) and self-report (e.g., MMPI)	Perceived conditions not related to either behavioral or psychometric change indices
Truax (24)	80 hospitalized schizophrenic patients (4 groups) and institutionalized juvenile delinquents (4 groups)	24	Composite final outcome criterion (FOC) based on 8 measures (e.g., MMPI, time out of institution, Q-sort adjustment)	Perceived C and U related to FOC; E and R not related
Truax and associates (25)***	63 hospitalized psychiatric patients	—	Hospitalization status, various Q-sorts, composite outcome index	Perceived E, warmth, and genuineness not related to outcome
Truax and associates (26)***	74 institutionalized male and female juvenile delinquents	—	Days institutionalized (1-year follow-up), Minnesota Counseling Inventory, various Q-sorts	Perceived E, warmth, and genuineness significantly related to all self-report measures, but not related to behavioral criterion (days out of institution)
Truax and associates (27)***	52 outpatients	—	MMPI, various Q-sorts	Perceived conditions significantly related to several but not all outcome criteria

*TH=therapist, P=patient, E=empathy, R=level of regard, U=unconditionality of regard, C=congruence, and T=total conditions. E,R,U,C, or T appearing in parentheses implies presumed equivalence with the relationship measure actually used.
**Used Truax Relationship Questionnaire (22). The authors reported two studies, the second being a replication of the first. Both "clients" (members "who were or had been in contact with the student psychiatric clinic or any other equivalent form of institution") and "nonclients" (students "interested in participating in a group experience") were included in the groups for these studies.
***As reported in Truax and Carkhuff (22); used Truax Relationship Questionnaire (22).

port measures in the FOC. Thus, on the basis of the findings presented it is impossible to determine whether perceived therapeutic conditions were differentially associated with these two importantly different sources of change evaluation. Comprehension of even the empirical meaning of Truax' data is even further obfuscated by his failure to report his findings on these two patient populations separately. In the second study (26), stronger support for the perceived-conditions–outcome hypothesis was found. Almost all self-report measures were significantly correlated with perceived conditions, but hospitalized recidivism was unrelated to these perceptions.

Only the group therapy study of Anderson and associates (18) found consistently positive relationships between perceived conditions and rated outcome. Studying hospitalized schizophrenic patients with more acute disturbances than in any other of the studies of

inpatients, Anderson and associates found significant relationships between patient-perceived therapist "understanding" and "interest" (according to ratings on 6-point scales) and patient satisfaction with treatment.

DISCUSSION

In sum, the client-centered perceived-conditions–outcome hypothesis has generally failed to be confirmed in the context of group therapy with both inpatients and outpatients. This finding is indeed striking when contrasted to the overwhelming support for the hypothesis in a wide variety of individual therapy contexts. One of us (A.S.G.) found support for the perceived-conditions–outcome hypothesis in 23 of 26 studies of individual therapy and counseling reported in the literature (30). Why then does the hypothesis fail to be confirmed in the studies of group therapy? Does this result mean that group therapy has essential differences from individual therapy?

Direct evidence in support of any specific interpretation of this difference is meager. Certainly the therapeutic rationale for a given school of group therapy can emphasize either the similarity or the difference from individual therapy and then technically exploit the similarity or the difference, as we described earlier. We also think that variables other than the theoretical stance of the group therapist influence whether the group approximates individual therapy or departs from it.

Given these possible differences in group therapy technique and strategy and their import for outcome, we have been very surprised and then very critical of the virtual absence of sufficient descriptions of group therapy technique in the studies we reviewed. Most of the studies did not even raise the matter of technique, and the few that did merely summarized the technique in a sentence or two and in a cursory manner that left the reader wondering how the group actually functioned. The failure to confirm Rogers' hypothesis, then, may simply be a function of how these groups were managed, i.e., they were not managed in a way that would make central the client-centered triad of therapist qualities. Without an adequate description of technique and without some report of the actual processes of these groups we have no way of sorting out group therapies that might confirm the hypothesis from those which might not. As is common to all early empirical research of any new subject, dimensions that are very different in kind get mixed together indiscriminately so that no clear correlation with outcome can be expected. It seems clear that group therapy research must begin to clarify the major differences in technique so that the effects of each kind of intervention can be examined separately. Lieberman and associates' *Encounter Groups: First Facts* (14) is a welcome model for this direction; we feel that this model should now be followed in group therapy proper.

How may group therapy depart significantly from individual therapy and thus be more likely to disconfirm the client-centered hypothesis? First, as we have stated, the therapeutic strategy may systematically deemphasize the role of the leader and emphasize the peer relations within the group. The group therapist may become a shadowy figure by design and may avoid interpretation of his or her position in the group. Second, even though the leader may intend to emphasize his or her relations with the group, the group may choose to deemphasize the leader. There are several ways in which this can happen: the group may constructively revolt and proceed to work independently and well, so that the therapist allows this process to continue (31); or the group may become pleased with its own curative powers and come to regard itself as a "Utopian" group (32) that wishes to exclude the establishment figure of the therapist. Surely all group therapists are familiar with phases of this kind of group activity. Third, the group situation may produce dangers different from individual therapy that require the therapist to be much more than empathic, warm, and genuine. The group may become quite vicious in its treatment of some members, or one or several of the members may show difficulties that are very frightening to the group. In these situations, the therapist must demonstrate rather forceful qualities if the group situation is to remain viable. If these kinds of problems are recurrent, the group therapist must repeatedly demonstrate certain qualities, including forceful and firm intervention, which might become his most important perceived qualities for the group members in relation to therapy outcome. These perceived qualities might become much more important than the perceived client-centered triad and thus explain disconfirmation of the Rogerian hypothesis.

Conversely, how may group therapy approximate individual therapy and be more likely to confirm Rogers' hypothesis? First, the technique may center on leader-client relations, as we have stated. Second, the group may defend itself in the group situation by idealizing the therapist (16) and emphasizing his or her personal goodness. Third, the group may avoid the dangers that are more likely to demand other attributes from the leader. The group may avoid confusion by a very explicit therapeutic language (like transactional analysis) and thus require less of the leader's intellectual abilities; it may avoid frightening situations with individual members by such therapeutic rituals as turn-taking or by careful preselection of members. In these ways, something like individual therapy may characterize a group and lead to confirmation of the importance of those perceived therapist conditions which are important in individual therapy.

This discussion should also suggest why cognitive structuring may be more important in group therapy than in individual therapy (14) and why it may be a necessary precondition for the operation of the variables of therapist empathy, warmth, and genuineness. Unless a group is sufficiently controlled and restrained by a common vocabulary, ritual, and intellectual belief

about how the therapy and the group works, the therapist is unlikely to be able to assume a role as a good empathic father or mother or be perceived as such. He or she will need, instead, to expend considerable effort and attention in managing other aspects of the group situation and be less available for relations with each individual in the group. Hence, the members are less apt to perceive the leader as empathic to individual concerns.

CONCLUSIONS

We argue that Rogers' hypothesized relationship between patient perceptions of the therapeutic relationship and treatment outcome, as applied to group therapy, cannot be meaningfully studied without consideration and control of several other salient variables. In general, we predict that the client-centered hypothesis probably would be confirmed only for groups that center on leader-client relations, that idealize the leader, and that are relatively untroubled by major group difficulties. The absence of major difficulties would probably presuppose a clearly explicit therapeutic ideology adopted by the group members. Progress in clinically relevant group therapy research, as in individual therapy research (33), is dependent on more sophisticated specification and control of variables in order to demonstrate their unique contribution to treatment outcome. Confirmation or disconfirmation of the client-centered hypothesis discussed here demands this kind of differential inquiry.

In Search of the True Amok: Amok as Viewed Within the Malay Culture

BY JOHN E. CARR, PH.D., AND ENG KONG TAN, M.B., B.S., M.P.M.

In an attempt to discover how the phenomenon of amok is viewed within its indigenous culture, the authors studied and interviewed 21 subjects in West Malaysia who were labeled as amok. This investigation showed that both the subjects and the Malay culture view amok as psychopathology, that amok cases are disposed of in line with this view, and that the behavior of the amok person conforms to social expectations of the phenomenon. Despite cultural proscriptions, however, the act is purposive and motivated and is subtly sanctioned by Malay society.

THE PHENOMENON OF amok has fascinated Western travelers, government officials, and social scientists for over two centuries, as evidenced by the large body of literature devoted to its description (1). The term "amok" refers to a violent or furious assault of homicidal intensity and is associated with the indigenous peoples of the Malay archipelago, although incidents of the amok syndrome have been reported as far east as New Guinea (2) and north into Laos (3).

In the past decade the phenomenon has come to the attention of transcultural researchers (4–7), who view amok as a form of behavioral disorder, specifically a "culture-bound reactive syndrome" (5). According to Yap, "certain systems of implicit values, social structure, and obviously shared beliefs produce unusual forms of psychopathology that are confined to special areas . . . although these are only atypical variations of generally distributed psychogenic disorders" (5, p. 38).

Despite this interest in amok, to our knowledge only three clinical studies of the disorder have been conducted in the Malay archipelago in the last 30 years (7, p. 41; 8, 9) and apparently none in which the phenomenon was investigated within the context of the belief system of the patient labeled as amok. The purpose of this study, therefore, was to locate, study, and interview a group of individuals defined as amok in order to identify how amok is viewed within the Malaysian culture. Specifically, we sought answers to the following questions:

1. Is amok viewed as a form of psychopathology within the culture in which it originates?
2. Is it viewed as such by the individuals who engage in the behavior?
3. Do the views of these individuals concur with the indigenous culture's definition of the phenomenon, its causes, course, and supporting values and beliefs?
4. Is the amok behavior of individuals considered amok consistent with that definition?

THE INDIGENOUS DIAGNOSTIC-DISPOSITION SYSTEM FOR AMOK

In Malaysia, as in any other country, murder and assault are civil crimes. However, no *pengamok* (one who runs amok) is to be found in the country's prisons. Instead, 21 amok subjects were found among the 134 patients of the male security ward of Hospital Bahagia, a large mental hospital in the town of Ulu Kinta in West Malaysia.

The designation "amok" was part of the patients' hospital records, which also revealed that in each of the 21 cases this designation was used by the local Malay police in the town in which the patient was originally apprehended. This labeling influenced a series of subsequent decisions resulting in confinement in a state mental hospital and entry into the Western psychiatric nosology system. Following arrest, the subject was remanded to the magistrate's court, where the judge received evidence from a district medical officer that the suspect was of "unsound mind" and incapable of a defense. Trial would then be postponed and the suspect remanded to the state hospital for observation, diagnosis, and treatment. Malay district medical officers have limited training and experience with psychiatric diagnosis, and physicians familiar with the procedure indicated to us that the designation of "unsound mind" was often based on the police report of the amok behavior and not infrequently was made without any examination of the patient. In each of the cases we studied, the magistrate was satisfied that the accused

Dr. Carr is Professor, Department of Psychiatry and Behavioral Sciences, and Director, Division of Psychology, University of Washington School of Medicine, Seattle, Wash. 98195. Dr. Tan is Lecturer, Department of Psychological Medicine, Faculty of Medicine, University of Malaya, Kuala Lumpur, Malaysia.

The authors wish to thank Dr. Edward Tan, Director, Hospital Bahagia, Ulu Kinta, Perak, Malaysia, and Prof. Tan Eng Seong, Head, Department of Psychological Medicine, University of Malaya, Kuala Lumpur, Malaysia, for their encouragement and assistance in the preparation of this paper, and Mr. Kwek, Hospital Assistant, Security Ward of Hospital Bahagia, and his staff for their help with interviews and data collection.

was "guilty but insane," i.e., incapable of knowing the nature of the act or that it was wrong. Therefore, each case was reported to the sultan or governor of the state, who ordered the offender confined in a mental hospital. Upon admission to the hospital, either for observation or longer term commitment, each patient received a psychiatric diagnosis (usually "schizophrenic") that was taken from the Western-oriented psychiatric nomenclature.

RECORD SEARCH AND INTERVIEWS WITH THE SUBJECTS

The hospital records of the 21 subjects were searched for data relevant to the amok incident. Following the collection of this material a standard interview of each patient was conducted jointly by the authors in the patient's native language. Each question and response was immediately translated into English and a second translator (a member of the hospital staff) was present at all times to validate the primary translation. The entire interview including translation was tape-recorded and subsequently rechecked for accuracy.

Following the interview each paitent was taken to a section of the ward where he could not discuss the nature of the interview with patients still waiting to be seen. None of the patients was informed of the purpose of the interview before being seen.

DESCRIPTION OF THE SUBJECTS

All the 21 patients we studied came from rural areas or small towns where, generally, police officers are Malay. Although all of the patients were products of this legal-cultural system of identification, they could be divided into the following three distinct groups: 1) those familiar with the term "amok" and nonpsychotic at the time of the interview, as judged by the authors and the ward supervisor (N=10); 2) those not familiar with the term "amok" and nonpsychotic (N=6); and 3) those clearly psychotic at the time of the interview (N=5).

Table 1 presents a descriptive summary of the amok incidents for each group. The patients in group 1 were all Malay, from rural areas, and employed in rural occupations, e.g., paddy planter. The patients in group 2 were Chinese or Indian, from urban areas, and were employed in mercantile occupations, e.g., shop clerk. The psychotic patients (group 3), who included 4 Malays and 1 Chinese, were generally from urban areas and unemployed or marginally employed.

Whereas for groups 1 and 2 the amok incidents span three decades, the group 3 incidents appear to be of more recent origin. The significance of this is unclear, although Murphy (7) has argued that placing amok within the context of the psychoses is a relatively recent development. An additional surprising and unexplained finding was that 50% of the incidents in groups 1 and 2 occurred in the month of May.

Group 1 accounted for a higher average number of assaults (4.3 deaths and injuries) than either group 2 (2.5) or group 3 (2.2). It would appear that the choice of a victim was a function of ethnic origin and political status, i.e., Malays assaulted Malays and Chinese, Chinese assaulted Chinese and Indians, and Indians assaulted only Indians. Similarly, the choice of weapon seems to reflect the ethnic origin of the subject, with group 1 preferring the parang (a short sword or machete), while vocational tools are more in evidence in group 2.

Only group 1 approximates the classical description of the *pengamok*: Malay, age 30 or more, rural villager, committing multiple assaults, and using a parang, spear, or kris (curved dagger). By contrast, group 2, all Chinese, had no notion of the concept amok ("I am not familiar with that English term"), fewer victims, and more varied choice of weapons. These were men who murdered or assaulted in a fit of rage, had no culture-specific explanation for what they did, and were unfamiliar with the explanation provided by the Malay policeman. Such subjects hardly qualify as the true amok.

Group 3 subjects also have dubious qualifications as true amoks. They were primarily Malay (except one Chinese) but were marginally adjusted and unemployed prior to the amok incident. At the time of the interview, each was clearly psychotic and had been throughout the course of that hospitalization (range= 2–24 years). Whereas the patients in groups 1 and 2 had had a mean symptom-free period of 9.4 and 9.6 years respectively, the patients in group 3 had previously been free of symptoms for an average of 1.2 years. Thus the clinical descriptions of these patients appear to more closely approximate the criteria for chronic psychosis.

THE TRADITIONAL MALAY VIEW OF AMOK

The evidence we gathered supports the view that amok is considered a form of mental illness within the Malay culture. Whether or not a subject was amok, once labeled as such the culture channeled him into a psychiatric hospital. No amoks can be found in prisons, or, to our knowledge, in any nonpsychiatric institutions within Malaysia. They have committed crimes, but crimes considered to be the result of insanity. Nor is this merely a product of Western psychiatric diagnosis. Once the amok enters the psychiatric institution he is likely to be labeled "schizophrenic," but the system that leads him there has already made a judgment regarding his sanity without benefit of psychiatric evaluation.

This judgment is based upon Malay concepts of mental illness, which include a specific form of insanity called *gila mengamok*. *Gila mengamok* is considered an extreme form of *gila kena hantu* (insanity due to evil spirits) or *gila buatan orang* (insanity caused by

TABLE 1
Description of Three Groups of Patients Labeled Amok (N = 21)

Item	Group 1 (N=10)	Group 2 (N=6)	Group 3 (N=5)
Mental status at time of study	Normal	Normal	Psychotic
Age at time of study (average age in parentheses)	22–71 (41)	40–61 (55)	30–54 (36)
Ethnic origin	All Malay	4 Chinese, 2 Indian	4 Malay, 1 Chinese
Area of residence	Rural	Small town	Small town
Occupation	Rural-related	Mercantile	Unemployed or marginally employed
Date of amok incident	1946–1974	1951–1973	1961–1972
Age at time of amok incident (average age in parentheses)	21–42 (33)	30–43 (39)	25–30 (28)
Ethnic origin of victims	22 Malay, 21 Chinese	8 Chinese, 7 Indian	10 Malay, 1 Chinese
Weapons used in amok incident	Parang, kris, spear	Tools	Parang, tools
Plans regarding further hospitalization	Get out (N=5) Stay in (N=5)	Get out (N=5) Stay in (N=1)	Get out (N=1) Stay in (N=4)
Presence of family support	Yes (N=7) No (N=3)	Yes (N=3) No (N=3)	No (N=5)

witchcraft). Both are characterized by fits of violence and a superhuman ability to wreak destruction. In the extreme form of *gila mengamok* this may result in indiscriminate injury and death (10, 11).

COMPARISON OF THE VIEWS OF THE PENGAMOKS AND SOCIETY

Of the 10 nonpsychotic subjects interviewed who claimed familiarity with the term "amok," 9 emphatically insisted that amok was an illness. The term was also described as a state or an act that usually was related to illness, although one subject was not certain of this. These 10 subjects, who may be considered true amoks, were remarkably consistent in their definition of amok, as can be seen in appendix 1.

In important details the composite definition provided by these 10 true amoks is consistent with the traditional view of amok (12), i.e., a furious assault commonly found in Malay males, especially farmers and mountain dwellers, unrelated to suicide, drugs, or alcohol (none of which were ever mentioned by our subjects) but instead related to psychical stress in the form of fright, anger, grief, or nervous depression. The attacks are preceded by vertigo ("fever") and visions ("influences"), are directed against friend and foe alike, may last a few hours, and are followed by total amnesia and deep stuporous sleep for several days.

In one detail our subjects' view varied from the traditional view. Classical descriptions refer to the difficulty of stopping the attack. Force generally is thought to be required, often resulting in the death of the *pengamok*. Only 4 of our 10 true amoks maintained that force was required. Two indicated that persuasion could be successful, and 4 stated that the attack could stop spontaneously. This deviation from the classical definition may be a product of a select sample (i.e., survivors) or of a change in the nature of the phenomenon itself (7). The records we reviewed suggest that at least within the past 30 years persuasion has been a commonly attempted tactic by police in bringing a *pengamok* under control.

In general, the behavior of the *pengamok* was consistent with their own and their society's view of amok behavior. In addition to the deviation they showed regarding modes of cessation of the attack, we noted that while our subjects indicated that anything handy was suitable as a weapon, each, in fact, selected a traditional weapon—a parang, spear, or kris. This suggests behavior designed to fulfill tradition.

THE QUESTION OF PURPOSIVENESS

Both the traditional view of the amok attack and that obtained from our amok subjects maintain that the act is unconscious, indiscriminate, and without purpose. However, history and a close look at the behavior of our subjects suggest otherwise. Several writers have commented on the sanctions afforded by Malay culture for the carrying out of a vengeful act through amok (1, 7, 12). For a supposed nonpurposive and unconscious act, it declined dramatically in popularity when the societal response at one time changed from sanction to drastic punishment (e.g., being drawn and quartered) (12).

The records of our subjects revealed that several exhibited a remarkable degree of purposiveness. One subject made his way to three separate coffee houses, all known to be frequented by Chinese, and killed five Chinese. His record further indicated that he had expressed anger toward the Chinese in response to some Chinese having killed some Malays during the civil emergency of May 13, 1969. The date of this subject's amok was May 19, 1974. Another subject killed seven

Chinese and injured five. The police report stated that the subject indicated the cause of his amok to be "racial disharmony."

According to Mahathir (13), "amok represents the external physical expression of the conflict within the Malay . . . a spilling over, an overflowing of his inner bitterness" (p. 118). This results from the Malay's traditional courtesy and self-effacing behavior, which may lead others, interpreting such diffidence as weakness and inferiority, to take advantage of him. Since his training dictates that he should never reprimand another, the Malay gives way until, in some few instances, he can give way no more. This type of stress recently led to an explosive situation culminating in the riots of May 13, 1969, which Mahathir saw as a grand amok on the part of an embittered people.

Of course, the motive for amok is not always racial. Our case histories included reports of a Malay man who killed his Chinese wife and injured two Chinese men over suspected infidelity, a Malay who killed his religious teacher and injured the teacher's wife, two Malays who attacked their sisters-in-law, and another who killed a neighbor who was provoking him. Almost all of the victims were known to the amok and were sources of criticism, frustration, or provocation.

SOCIAL STIGMATIZATIONS OF THE PENGAMOK

On admission, 7 of the 10 true amok subjects showed inappropriate behavior, manifesting delusions and/or hallucinations. On the basis of these reports we may conclude that the patients' behavior was psychotic-like. The duration of that initial "psychotic" state did not exceed 9 months in any of the patients, and 6 of the 10 were symptom free for the remainder of their hospitalization. In spite of the brevity of such "psychosis," the period of hospitalization for group 1 ranged from 1 to 28 years, with an average stay of 12.4 years. The range and mean period of hospitalization were similar for groups 2 and 3.

Why were these men not released in view of their apparent recovery? Patients within the same institution who were also diagnosed as schizophrenic but not amok had a greater likelihood of release. Aside from legal questions, the fact that these men were not released indicates an important aspect of the Malay view of amok: not only is amok viewed as a form of mental illness, but it is considered an extremely threatening illness and is greatly feared by society. While we found no evidence of recidivism, the belief that this is possible leads to extended periods of hospitalization, with little hope of release. In several instances we found explicit evidence that the family and/or community was opposed to the patient's release.

It would appear that the potentially deleterious effects of labeling a person mentally ill may be similar regardless of whether the patient is a Malaysian diagnosed according to Malay concepts of mental illness or an American diagnosed in Western terms. If this is true, the issue in diagnosis should be not so much the question of its efficacy as it is finding common attributional characteristics among the indigenous concepts upon which diagnostic systems are based (14).

CONCLUSIONS

The evidence of this study supports Yap's view of amok as a "culture-bound reactive syndrome" (5). It shows that amok is a culturally specific, complex pattern of behaviors with identifiable antecedent and consequent conditions and that it is defined as psychopathology within the indigenous culture. Despite cultural proscriptions to the contrary, amok is purposive and motivated and is subtly sanctioned by the Malay culture as an appropriate mode of response to certain situations.

APPENDIX 1
Definition of Amok by the True Amoks (N=10)

Nature of amok: an illness (9 subjects supported this view), a state (2), an act (3).

Mental state of subject: unconscious and not responsible (9).

Preamok mental state: angry (5), normal (4), disturbed thoughts (3), anxious (2).

Causes of amok: evil spirits (4), influence of other people (3), threat (3), heat (3), God (3).

Amount of violence: always present, acute (10).

Targets: any living thing (10).

Fatalities: not necessary, any number (10).

Weapons: anything handy (10).

Reason for cessation: force (4), spontaneous recovery (4), persuasion (2).

Postamok condition of subject: amnesia (7), exhaustion (3), disturbed (2), regret (1).

Possibility of relapses: can relapse (9), but no cases known to subjects or authors (10).

Type of victims: any age, race, or sex (10).

Family response: fear (4), sympathy (4), sadness (3), depression (2).

Community response: fear (6), do not know (3), anger (2).

A New Section in the *Journal*

The *Journal* is pleased to announce the inauguration of a new section, "Clinical and Research Reports," which will appear monthly beginning with the January 1977 issue. This section will include reports on new clinical or laboratory observations, single cases of unusual interest or importance, descriptions of preliminary studies, and well-developed suggestions for future research. Reports should not exceed 1,000 words and may contain at most 1 table and 8 pertinent references (figures will not be used). Submissions will be reviewed by at least one referee and the Editor. It is anticipated that the publication lag will be considerably less for Reports than for other articles in the *Journal*. Submissions are welcome immediately; authors will be informed by postcard of the disposition of their papers.

Reports should be submitted in duplicate, double-spaced, with tables and references typed on separate sheets. The designation "Clinical and Research Reports" should appear in the upper right corner of the title page, and complete addresses and affiliations, as well as a telephone number of the author designated to handle correspondence, are required.

Can Program Evaluation Be Saved from Its Enthusiasts?

BY JACK ZUSMAN, M.D.

Program evaluation—the use of scientific techniques to measure the value of an agency's work—has become the focus of major attention and enthusiasm in mental health service planning and administration. However, the author points out that completed program evaluation studies are few in number and provide no evidence of great impact on the operation of programs or agencies and that unrealistic enthusiasm for program evaluation can lead to unrealistic rejection when performance fails to reach promise. He concludes that program evaluation should be applied only when it can have an impact, i.e., in a limited number of carefully selected cases.

PROGRAM EVALUATION—the use of scientific techniques to measure the value of an agency's work—has become a major concern on the current mental health service scene. Evaluation of every mental health service program is increasingly coming to be looked on as essential in order to maintain public support and as a means of budgetary salvation when costs are increasing and available funds are decreasing.

Top-level government officials seem to encourage widespread use of program evaluation without reservation (1). Proponents of the community mental health center movement have suggested that program evaluation studies will be one of the most important means of convincing the public that centers are doing their jobs (2, p. 5). At least one state, California, has enacted a law requiring program evaluation of state-supported mental health service programs (3). New York State has several provisions in its mental hygiene law that support program evaluation, although they do not clearly require it (4). New York also has a unit that includes program evaluation among its statewide responsibilities (5).

There is a strong movement toward requiring program evaluation of every federally funded service (6, p. 15). Mental health centers now quite commonly have evaluation specialists or units within their organizations or as consultants. There are major federal efforts under way to popularize the evaluation concept and spread information about the usefulness of and techniques for evaluation, including publication of the journal *Evaluation*, sponsoring of a national conference on the subject in 1974, and publication of resource materials (7). Not surprisingly, administrators of mental health programs are under pressure to evaluate all aspects of their programs; few new programs are designed without "built-in evaluation." One author (8) has even called evaluation (in an at least semi-serious vein) a "panacea."

Program evaluation itself has thus become a major element of programs, one that is usually instituted with great enthusiasm and prediction of important effects. However, the fact is that response to results of completed program evaluation studies is often honored more in the breach than in the observance and for a very good reason: program evaluation studies have so far demonstrated little of value to mental health service administrators or, for that matter, to administrators in any of the social welfare fields and are unlikely to do so for some time to come.

Indeed, in view of numerous reports of the failure of various governmental efforts at service evaluation and quality control in other areas (9–13), it would seem that the burden of proof ought to be on anyone who predicts that mental health program evaluation studies will be effective in improving service. (Although many reports of failure of governmental evaluation and enforcement efforts are journalistic and almost none meet any sort of standard for a scientific investigation, they nonetheless make up an imposing collection. The references provided here represent only a fraction of those which could have been listed.)

There are several fundamental reasons for the lack of accomplishment of program evaluators and program evaluation studies so far (14, 15). In view of the tremendous fanfare that has been generated by program evaluation, it is essential to examine this situation with care.

THE PROGRAM EVALUATION PROCESS

Many definitions of program evaluation exist (16–18), but the essential element, whatever the definition, seems to be the use of scientific methods to examine the work or accomplishment of an agency in relation to an agreed on set of standards. The agency's work may be examined in a number of ways and at a number of points in the work process. One convenient manner of categorizing evaluation approaches is that offered by

Dr. Zusman is Medical Director, Gateways Hospital, 1891 Effie St., Los Angeles, Calif. 90026; he is also Clinical Professor of Psychiatry, University of Southern California School of Medicine, Los Angeles, Calif.

Donabedian (19), which was later applied specifically to mental health services by Zusman and Ross (20). Donabedian divided evaluation into examination of structure, i.e., working tools of the agency, such as office space, staff, record keeping, and administrative procedures; process, i.e., interaction between staff and patients; and outcome, i.e., eventual result of the service provided.

Outcome evaluation is in a sense the best measure because it answers the question of whether the service did any good for the patient. However, because outcome is the most expensive, complicated, and long-term form of program evaluation, it is often more practical to study structure and process. The latter two approaches are based on two assumptions: that good structure and process in a program will lead to good outcome—often a very tenuous but commonly accepted assumption—and that experts are able to agree on and specify accurately the characteristics of good structure and process.

Scientific methods are used in program evaluation, but the process begins with quantifying the nonscientific values and goals implicit in an agency's work. These values and goals arise from political, ethical, and moral beliefs. As a neutral method for discovering facts, science has no place in this most basic aspect of evaluation; therefore, evaluation is at best only partially a scientific activity.

Selecting goals of an agency or program against which its accomplishments will be measured may be done through obtaining consensus among professionals; studying desires of the individuals served by the program; responding to wishes of the political leaders who ultimately control the agency's budget; a combination of these; or any number of other possible mixtures of sociopolitical forces. Selection of the particular goals, which are not necessarily congruent with the work the agency is prepared to do or actually is doing, can determine even before the study is undertaken whether it will show negative or positive results (21, p. 258). By choosing a goal impossible for the agency to attain or one that unquestionably has already been attained, the evaluator or administrator has the power covertly to control a result that will seem to emerge independently from data analysis months or years later.

It is important to distinguish the form of program evaluation under discussion here from two other kinds of activities commonly confused with it. Management information, which has also been called "effort evaluation" (22, p. 37), is accounting and analysis of such everyday administrative items as patient flow, agency income and expenditure, and staff time use. Whereas program evaluation measures accomplishments against a set of goals, involves acceptance of a number of untested assumptions, and often does not produce information until long after the service has been completed, management information simply provides value-free statistics regarding current service demands and resource use within the agency. A management information system is an essential part of every agency administration because it enables the program manager to monitor and control his or her staff. It is not program evaluation, in that it measures only the "spinning of the wheels" and does not indicate anything about quality or accomplishment. On the positive side, however, management information costs very little beyond the cost of regular agency operation, requires little in the way of trained staff to produce, and is simple to understand and respond to.

The second activity to be distinguished from program evaluation is "rapid informal evaluation" (23), or quality estimation. (There is no commonly accepted term for this activity; little has been published about it.) Informal evaluation of service quality is carried out by every professional considering and improving his or her own work and the work of other professionals with whom he or she is in contact. We all have our own standards of care developed over our years of professional experience. When formal evaluation of a program is yet to be done, these standards often can and should serve as guides for service improvement.

Many lapses in service quality do not require elaborate studies to pinpoint them. Brief, informal observation serves as well (24, 25). A common failure has been to assume that service quality cannot be studied or improved without formal program evaluation. Nothing could be farther from the truth. Informal quality estimation, like management information, must be part of every administrative operation. It too is inexpensive, easily and quickly done, and simple to respond to. Its major drawbacks are its lack of public, easily stated standards and the arbitrariness behind the standards.

STUDIES AND EXAMPLES

Program evaluation studies in mental health have thus far accomplished little, in part because few have been completed and reported. However, a small number of studies has been reported whose effects can be examined as examples of what the impact of a program evaluation study can be. In addition to these examples, a number of episodes of evaluation-type incidents in mental health and related fields are similar enough in effect to formal evaluations to be looked on as suggestive of difficulties that program evaluation studies will encounter.

Among the success stories of the impact of a positive program evaluation (limited though the success may have been) has been the demonstration by several investigators of the effectiveness of brief psychiatric hospitalization for severe mental illness in contrast to the debilitating effect of prolonged hospitalization (26). Although there was never any crucial single study of this phenomenon, beginning in the late 1940s there were a number of clear demonstrations and "experiments of nature" that provided strong evidence (27–30). The use of brief rather than long-term hospitalization has spread widely on the basis of re-
